Finally, in energy-driven processes, the energy is largely required to overcome the latent heat of phase change. Other things being equal, this favors heats of fusion over heats of vaporization and choice of selective solvents having lower heats of phase change in their recovery process. The use of multi-effect temperature cascades in the separation process can reduce the advantage offered by using low latent heat processes. While these rules of thumb are helpful in preliminary choices of separation processes, it must be remembered that the optimum separation process involves a balance between energy costs and the costs for equipment to minimize energy costs. Therefore, sometimes, it is desirable to pay for more energy and with the additional capital costs and operating complexity necessary to achieve high thermal efficiency.

Rectisol Process

The Rectisol process is a physical solvent gas treating process. The process uses chilled methanol (methyl alcohol, CH_3OH) at a temperature of approximately -40°F to -80°F . The selectivity (by methanol) for hydrogen sulfide over carbon dioxide at these temperatures is approximately 6/1, a little lower than that of the Selexol process at its usual operating temperature. However, the solubility of hydrogen sulfide and carbonyl sulfide in methanol, at typical process operating temperatures, is higher than in Selexol and allows for very deep sulfur removal. The high selectivity for hydrogen sulfide over carbon dioxide, combined with the ability to remove carbonyl sulfide, is the primary advantage of the process. The need to refrigerate the solvent is the main disadvantage of the process, resulting in high capital and operating costs. There are many possible process configurations for the Rectisol process, depending on process requirements. Different process layouts are used for selective hydrogen sulfide removal, and carbon dioxide, and for non-selective carbon dioxide and hydrogen sulfide.

The process is designed for the bulk removal of carbon dioxide, and nearly all of the removal of hydrogen sulfide and carbonyl sulfide takes place in the bottom section of the absorber. The methanol solvent contacting the feed gas in the first stage of the absorber is stripped in two stages of flashing via pressure reduction. The regenerated solvent is virtually free of sulfur compounds but contains some carbon dioxide. The acid gas leaving the first-stage solvent regenerator is suitable for a Claus plant. The second stage of absorption is designed for the removal of the remaining sulfur compounds and carbon dioxide. The solvent from the bottom of the second stage of the absorber is stripped deeply in a steam-heated regenerator and is returned to the top of the absorption column after cooling and refrigeration.

Redox Processes

A redox reaction is a type of chemical reaction in which the oxidation states of atoms are changed. Redox reactions are characterized by the actual or formal transfer of electrons between molecules. Thus, a redox process denotes a process in which there is a coupled reduction reaction and oxidation reaction, i.e., an electron transfer reaction where reduction is the uptake of electrons and oxidation is the release of electrons.

As an example of a redox process, liquid redox sulfur recovery processes are liquid-phase oxidation processes which use a dilute aqueous solution of iron or vanadium to remove hydrogen sulfide selectively by chemical absorption from sour gas streams. These processes can be used on relatively small or dilute hydrogen sulfide stream to recover sulfur from the acid gas stream, or, in some cases, they can be used in place of an acid gas removal process. The mildly alkaline lean liquid scrubs the hydrogen sulfide from the inlet gas stream, and the catalyst oxidizes the hydrogen sulfide to elemental sulfur. The reduced catalyst is regenerated by contact with air in the oxidizer(s). Sulfur is removed from the solution by flotation or settling, depending on the process.

Reed Canary Grass

Reed canary grass is a robust perennial grass, widely distributed across temperate regions of Europe, Asia, and also North America. It occurs in wet places, along the margins of rivers, streams, lakes, and pools. The species spreads naturally by creeping rhizomes, but plants can also be raised from seed. The advantages of Reed Canary grass as an energy crop are its good adaptation to cool temperate climates and poor wet soil conditions and, conversely, its ability to withstand drought. Crucially, for the purposes of biomass production, reed canary grass is also able to attain high dry matter content earlier than *Miscanthus*. The crop responds well to nitrogen and phosphate, and it may be used in a bed system to remove nutrients from wastewater, as well as to stabilize areas at risk of soil erosion.

This rhizomatous grass can grow up to six feet in height and usually flowers in June and July. Reed canary grass is usually harvested once per year either by mowing or baling using a high-density baler. Crop duration of 10 years or more may be possible. Due to its low moisture content, canary grass (those harvested in spring) can be easily converted to pellets, briquettes, and powder.

The advantages of reed canary grass as an energy crop are its good adaptation to cool temperate climates and poor wet soil conditions and, conversely, its ability to withstand drought. Crucially, for the purposes of biomass production, reed canary grass is also able to attain high dry matter content earlier than *Miscanthus*. The crop responds well to nitrogen and phosphate, and it may be used in a bed system to remove nutrients from wastewater, as well as to stabilize areas at risk of soil erosion.

Reed Plants

Reed is a common name for several tall, grass-like plants that are commonly found in wetlands. Reed plants are a potentially prolific producer of biomass, capable of yielding 20 to 25 tons per hectare (2.47 acres) of dry matter annually for a number of years. They can grow up to 6 m, are spread by means of stout rhizomes (continuously growing horizontal underground stems, which puts out lateral shoots and adventitious roots at intervals) and stolons (also known as runners, which are horizontal connections between organisms), and are commonly found in swampy ground and shallow water throughout temperate and subtropical areas.

Common reeds grow well in damp ground or standing water, with stems up to 12 feet in height. It prefers full sun but can stand some partial shade. It requires an alkaline or neutral pH condition, not surviving in acidity. Wetland areas will see much reed bed growths. The leaves are an interesting color of blue green and are sharp to the touch. The flowers are small, usually only an inch wide, but the reed is commonly grown more for its foliage during the seasons for the blooms on it.

Reed plants may contain high amounts of heavy metals, and the heavy metals content appears to be inversely related to the sediment clay and/or organic matter content. Metal mobility and thus plant availability are higher in sediments with lower clay or organic matter content or a high salinity. Moreover, the plants might actively accumulate in particular essential elements when concentrations in the sediments are rather low, which is the case in sediments low in clay and organic matter contents.

On the other hand, reed plants have other uses such as phytoremediation, which is the use of plants and their associated microorganisms, to remove, contain, or degrade chemical contaminants from the environment. It is an

emerging technology for environmental remediation that offers promise as a low-cost, flexible technique suitable for use against a number of different types of contaminants in a variety of media. This illustrates the applicability of using reed plants in removing pollutants from contaminated water.

Refinery Gas

The terms *refinery gas* and *petroleum gas* are often used to identify liquefied petroleum gas or even gas that emanates as light ends (gases and volatile liquids) from the atmospheric distillation unit or from any one of several other refinery processes.

For the purpose of this text, refinery gas not only describes liquefied petroleum gas but also natural gas and refinery gas. However, the composition of each gas varies and recognition of this is essential before the relevant testing protocols are selected and applied. Thus, refinery gas (fuel gas) is the non-condensable gas that is obtained during distillation of crude oil or treatment (cracking, thermal decomposition) of petroleum.

Refinery gas is produced in considerable quantities during the different refining processes and is used as fuel for the refinery itself and as an important feedstock for the production of petrochemicals. It consists mainly of hydrogen (H_2), methane (CH_4), ethane (C_2H_6), propane (C_3H_8), butane (C_4H_{10}), and olefins ($RCH=CHR^1$, where R and R^1 can be hydrogen or a methyl group) and may also include off-gases from petrochemical processes (Table 3.9). Olefins such as ethylene ($CH_2=CH_2$, boiling point: $-104^\circ C$, $-155^\circ F$), propene (propylene, $CH_3CH=CH_2$, boiling point: $-47^\circ C$, $-53^\circ F$), butene (butene-1, $CH_3CH_2CH=CH_2$, boiling point: $-5^\circ C$, $23^\circ F$), *iso*-butylene ($(CH_3)_2C=CH_2$, $-6^\circ C$, $21^\circ F$), *cis*- and *trans*-butene-2 ($CH_3CH=CHCH_3$, boiling point: ca. $1^\circ C$, $30^\circ F$), and butadiene ($CH_2=CHCH=CH_2$, boiling point: $-4^\circ C$, $24^\circ F$) as well as higher-boiling olefins are produced by various refining processes.

Still gas is broad terminology for low-boiling hydrocarbon mixtures and is the lowest boiling fraction isolated from a distillation (*still*) unit in the refinery. If the distillation unit is separating light hydrocarbon fractions, the still gas will be almost entirely methane with only traces of ethane (CH_3CH_3) and ethylene ($CH_2=CH_2$). If the distillation unit is handling higher-boiling fractions, the still gas might also contain propane ($CH_3CH_2CH_3$), butane ($CH_3CH_2CH_2CH_3$), and their respective isomers. *Fuel gas* and still gas are terms that are often used interchangeably, but the term *fuel gas* is intended to denote the product's destination – to be used as a fuel for boilers, furnaces, or heaters.

A group of refining operations that contributes to gas production are the thermal cracking and catalytic cracking processes. The thermal cracking processes (such as the coking processes) produce a variety of gases, some of which may contain olefin derivatives ($>C=C<$). In the visbreaking process, fuel oil is passed through externally fired tubes and undergoes liquid-phase cracking reactions, which result in the formation of lower-boiling fuel oil components. Substantial quantities of both gas and carbon are also formed in coking (both fluid coking and delayed coking) in addition to the middle distillate and naphtha. When coking a residual fuel oil or heavy gas oil, the feedstock is preheated and contacted with hot carbon (coke) which causes extensive cracking of the feedstock constituents of higher molecular weight to produce lower-molecular-weight products ranging from methane, via liquefied petroleum gas(es) and naphtha, to gas oil and heating oil. Products from coking processes tend to be unsaturated, and olefin-type components predominate in the tail gases from coking processes.

The various catalytic cracking processes, in which higher-boiling gas oil fractions are converted into gaseous products, various naphtha fractions, fuel oil, and coke by contacting the feedstock with the hot catalyst. Thus, both catalytic and thermal cracking processes, the latter being now largely used to produce chemical raw materials, result in the formation of unsaturated hydrocarbon derivatives, particularly ethylene ($CH_2=CH_2$), but also propylene (propene, $CH_3CH=CH_2$), isobutylene [isobutene, $(CH_3)_2C=CH_2$], and the *n*-butenes ($CH_3CH_2CH=CH_2$, and $CH_3CH=CHCH_3$) in addition to hydrogen (H_2), methane (CH_4), and smaller quantities of ethane (CH_3CH_3), propane ($CH_3CH_2CH_3$), and butane isomers [$CH_3CH_2CH_2CH_3$, $(CH_3)_3CH$]. Diolefins such as butadiene ($CH_2=CHCH=CH_2$) are also present.

In a series of reforming processes, distillation fractions which include paraffin derivatives, and naphthene derivatives (cyclic non-aromatic) are treated in the presence of hydrogen and a catalyst to produce lower-molecular-weight products or are isomerized to more highly branched hydrocarbon derivatives. Also, the catalytic reforming process

not only results in the formation of a liquid product of higher octane number but also produce substantial quantities of gaseous products. The composition of these gases varies in accordance with process severity and the properties of the feedstock. The gaseous products are not only rich in hydrogen but also contain hydrocarbon derivatives from methane to butane derivatives, with a preponderance of propane ($\text{CH}_3\text{CH}_2\text{CH}_3$), n-butane ($\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3$), and isobutane [$(\text{CH}_3)_3\text{CH}$]. Since all catalytic reforming processes require substantial recycling of a hydrogen stream, it is normal to separate reformer gas into a propane ($\text{CH}_3\text{CH}_2\text{CH}_3$) and/or a butane [$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3/(\text{CH}_3)_3\text{CH}$] stream, which becomes part of the refinery liquefied petroleum gas production, and a lower-boiling gaseous fraction, part of which is recycled.

A further source of refinery gas is produced by the hydrocracking process which is a high-pressure pyrolysis process carried out in the presence of fresh and recycled hydrogen. The feedstock is again heavy gas oil or residual fuel oil, and the process is mainly directed at the production of additional middle distillates and gasoline. Since hydrogen is to be recycled, the gases produced in this process again must be separated into lighter and heavier streams; any surplus recycle gas and the liquefied petroleum gas from the hydrocracking process are both saturated.

Both hydrocracker and catalytic reformer tail gases are commonly used in catalytic desulfurization processes. In the latter, feedstocks ranging from light to vacuum gas oils are passed at pressures on the order of 500 to 1,000 psi with hydrogen over a hydrofining catalyst. This results mainly in the conversion of organic sulfur compounds to hydrogen sulfide:

The process also has the potential to produce lower-boiling hydrocarbon derivatives by hydrocracking.

Refinery gas, usually in more than one stream, is typically treated for hydrogen sulfide removal, and gas sales are usually on a thermal content (calorific value, heating value) basis with some adjustment for variation in the calorific value and hydrocarbon type.

See also: Refining.

Refinery Waste

In spite of a refinery being a site for the conversion of fossil fuels (natural gas and crude oil) into valuable products, a refinery also produces a variety of waste material that can also be converted into useful products. For this reason, a refinery can be considered to be a source of energy from alternate sources.

Crude oil refining is the physical, thermal, and chemical separation of crude oil into its major distillation fractions which are then further processed through a series of separation and conversion steps into finished crude oil products. The primary products of the industry fall into three major categories which are (i) fuels, such as motor gasoline, diesel and distillate fuel oil, liquefied petroleum gas, jet fuel, residual fuel oil, kerosene, and coke, (ii) finished non-fuel products, such as solvents, lubricating oils, greases, crude oil wax, crude oil jelly, asphalt, and coke, and (iii) chemical industry feedstocks, such as ethane, propane, butane, ethylene, propylene, butylenes, butadiene, benzene, toluene, and xylene, and naphtha. These crude oil products are used as primary input to a vast number of products, including fertilizers, pesticides, paints, waxes, thinners, solvents, cleaning fluids, detergents, refrigerants, antifreeze, resins, sealants, insulations, latex, rubber compounds, hard plastics, plastic sheeting, plastic foam, and synthetic fibers.

The chemicals in crude oil vary from simple hydrocarbons of low-to-medium molecular weight to higher-molecular-weight organic compounds containing sulfur, oxygen, and nitrogen, as well as compounds containing metallic constituents, particularly vanadium nickel, iron, and copper. Many of these latter compounds are of indeterminate molecular weight. Residua contain significantly less hydrocarbon constituents than the original crude oil. The constituents of residua may, depending on the crude oil, be molecular entities of which the majority contains at least one heteroatom.

Typical refinery products include (i) natural gas and liquefied petroleum oil gas (LPG), (ii) solvent naphtha, (iii) kerosene, (iv) diesel fuel, (v) jet fuel, (vi) lubricating oil, (vii) various fuel oils, (viii) wax, (ix) residua, and

(x) asphalt. A single refinery does not necessarily produce all of these products. Some refineries are dedicated to particular products, e.g., the production of gasoline or the production of lubricating oil or the production of asphalt. However, the issue is that refineries also produce a variety of waste products that must be disposed in an environmentally acceptable manner.

Waste treatment processes also account for a significant area of the refinery, particularly sulfur compounds in gaseous emissions together with various solid and liquid extracts and wastes generated during the refining process. The refinery is therefore composed of a complex system of stills, cracking units, processing and blending units, and vessels in which the various reactions take place, as well as packaging units for products for immediate distribution to the retailer, e.g., lubricating oils. Bulk storage tanks usually grouped together in tank farms are used for storage of both crude and refined products. Other tanks are used in the processes outlined, e.g. treating, blending, and mixing, while others are used for spill and fire control systems. A boiler and electrical generating system usually operate for the refinery as a whole.

There are several hundred individual hydrocarbon chemicals defined as crude oil-based. Furthermore, each crude oil product has its own mix of constituents because crude oil varies in composition from one reservoir to another, and this variation may be reflected in the finished product(s).

Crude oil hydrocarbons are environmental contaminants, but they are not usually classified as hazardous wastes. Soil and groundwater crude oil hydrocarbon contamination has long been of concern and has spurred various analytical and site remediation developments, e.g., risk-based corrective actions. In some instances, it may appear that such clean-up operations were initiated with an incomplete knowledge of the character and behavior of the contaminants. The most appropriate first assumption is that the spilled constituents are toxic to the ecosystem. The second issue is an investigation of the products of the spilled material to determine an appropriate clean-up method. The third issue is whether or not the chemical nature of the constituents has changed during the time since the material was released into the environment. If it has, a determination must be made of the effect of any such changes on the potential clean-up method.

Despite the large number of hydrocarbons found in crude oil products and the widespread nature of crude oil use and contamination, many of the lower boiling constituents are well characterized in terms of physical properties, but only a relatively small number of the compounds are well characterized for toxicity. The health effects of some fractions can be well characterized based on their components or representative compounds (e.g., a low-boiling aromatic fraction benzene-toluene-ethylbenzene-xylenes). However, higher-molecular-weight (higher-boiling) fractions have far fewer well-characterized compounds.

See also Refining.

Refining

Crude oil refining is the separation of petroleum into fractions and the subsequent treating of these fractions to yield marketable products. In fact, a refinery is essentially a group of manufacturing plants which vary in number with the variety of products produced. Refinery processes must be selected and products manufactured to give a balanced operation in which petroleum is converted into a variety of products in amounts that are in accord with the demand for each. For example, the manufacture of products from the lower-boiling portion of petroleum automatically produces a certain amount of higher-boiling components. If the latter cannot be sold as, say, heavy fuel oil, these products will accumulate until refinery storage facilities are full. To prevent the occurrence of such a situation, the refinery must be flexible and be able to change operations as needed. This usually means more processes: thermal processes to change an excess of heavy fuel oil into more gasoline with coke as the residual product, or a vacuum distillation process to separate the heavy oil into lubricating oil blend stocks and asphalt.

The primary products of refining fall into three major categories: fuels (motor gasoline, diesel and distillate fuel oil, liquefied petroleum gas, jet fuel, residual fuel oil, kerosene, and coke). Non-fuel products (such as solvents, lubricating oils, greases, wax, asphalt, and coke) and chemical industry feedstocks (such naphtha, ethane, propane, butane, ethylene, propylene, butylenes, butadiene, benzene, toluene, and xylene) are also produced.

Refuse-Derived Fuel

Refuse-derived fuel (RDF) is fuel prepared from municipal solid waste after which any noncombustible materials such as rocks, glass, and metals are removed, leaving the remaining combustible portion of the solid waste chopped or shredded. Because of the potential for the inclusion of hazardous materials, the fuel is often categorized accordingly (Table R-14).

Table R-14 General categories of refuse-derived fuel.

Category	Common name	Description
RDF-1		Municipal solid wastes (MSW) used as a fuel in the discarded form
RDF-2	Coarse Fluff RDF	MSW processed to coarse particle size with or without ferrous material
RDF-3	Fine Fluff RDF	Shredded fuel derived from MSW that has been processed
RDF-4	Powdered RDF	Combustible waste processed into powdered form
RDF-5	Densified RDF	Combustible waste densified (compressed) into the form of pellets
RDF-6		Combustible waste processed into liquid fuel
RDF-7		Combustible waste processed into gaseous fuel

This is a result of processing municipal solid waste, facilitating recycling, re-use, and ensuring the homogenous nature of the waste. The non-combustible elements of the waste are left over after processing, giving the waste a higher calorific value. The new improved composition of the waste allows increased efficiency from incineration and reduced emissions and products as the waste that creates the harmful effects can be removed during processing.

The types of materials to be processed are the various combustible components, and such components include non-recyclable plastics, paper cardboard, labels, and generally corrugative materials. Because RDF can process such a variety of materials, there are different techniques to ensure the creation of a homogenous material that can be used as a substitute fossil fuel and act as a reduction agent in steel furnaces. The most common way of extracting refuse-derived fuel from municipal solid waste is to combine mechanical and biological treatment methods which include: (i) size screening, (ii) coarse shredding, (iii) bag splitting, (iv) shredding, (v) magnetic separation, and (vi) refining separation. Thus, the processing involves (i) separating unwanted components (for example by magnetically extracting ferrous metals), (ii) shredding, (iii) drying, and compacting the material into pellets. This type of processing allows fuel resources to become easily transported and more hygienically handled; it also allows incineration to play a part in waste management where reduction, reuse, and recycling can be maximized.

Further processing has also been developed; the end product is called densified refuse-derived fuel (d-RDF). This is a process by which the combustible part of the waste is separated, pulverized, compressed, and dried to produce solid fuel pellets that are approximately two inches long.

Refuse-derived fuel processes typically begin with shredding municipal solid waste to a finer size; many then separate the fuel fraction from the residue. In plants where no additional preparation is included, the operation is called a shred-and-burn refuse-derived fuel facility. Frequently, however, the separated fuel fraction is further processed to recover metals and sometimes glass. The normal sequence of refuse-derived fuel facility preparation is shredding, air classifying/screening, magnetic separation, and sometimes eddy current separation for nonferrous metal recovery. Many variations of the process have been developed, each of which has certain advantages.

Refuse-derived fuel is a useful feedstock for pyrolysis, gasification, and combustion since it grants a reasonably high heating value, suitable-sized particle size, and (in some cases) a more constant and homogeneous composition.

However, any differences in composition and the thermal degradation behavior make the process design, and operation of energy recovery units a challenge. Different waste require different treatments from pyrolysis to combustion, from fluffy material in fluidized bed to pellets, or briquettes in grate reactors. Thus, together with the combustion of different waste, the pyrolysis of waste tires to produce valuable oil, char, and gas products is of growing interest. Again, the most common reactors used are fixed-bed, screw and rotary kiln, vacuum, and fluid bed.

See also: Municipal Solid Waste, Scrap Tires, Waste.

Refuse Gas

There are two ways of producing gaseous fuel from refuse or waste: (i) gasification of the refuse at high temperatures by partial oxidation and then conversion of materials containing carbon into synthesis gas (mainly hydrogen and carbon monoxide) and (ii) production of biogas, mainly methane, by the anaerobic digestion of the refuse in a landfill.

The principle behind waste gasification and the production of gaseous fuels is that waste contains carbon and it is this carbon that is converted to gaseous products via the usual gasification chemistry. This, when fuel is fed to a gasifier, water and volatile matter are released fast and a char residue is left to react further. The char gasification is what mainly controls the conversion achieved in the process. From solid carbon, product gas is formed according to the following main reactions:

In addition to the reactions of solid carbon, the most important reaction is the water-gas shift reaction, which takes place in the gas phase:

The product gas generally contains large amounts of hydrogen and carbon monoxide and a small amount of methane, as well as carbon dioxide and steam, and in air gasification nitrogen. In addition, a significant amount of other organic components in the gas, known as tar, is formed. Tar formation is a well-known phenomenon in the thermal reactions of coal and can also be anticipated to form in the gasification or pyrolysis of any complex carbonaceous material.

See also: Energy Production from Waste, Fuels from Waste, Gaseous Fuels from Waste, Refuse-Derived Fuel.

Regenerative and Non-Regenerative Gas Cleaning Processes

The procedures for the removal of sulfur dioxide can be classified further as regenerative or non-regenerative, depending upon whether the chemical used to remove the sulfur dioxide can be regenerated and used again or whether the chemical is unusable and passes to disposal.

In the wet regenerative processes, either elemental sulfur or sulfuric acid is recovered. In the wet non-regenerative processes, using lime and/or limestone, calcium sulfite or calcium sulfate sludge is produced that is disposed. Wet scrubbing processes contact the flue gas with a solution or slurry for sulfur dioxide removal. In a wet limestone process, the flue gas contacts a limestone slurry in a scrubber:

Both the sulfite and the sulfate absorb water of hydration to form a sludge composed of sulfite and sulfate derivatives.

In a wet lime process, a gas stream containing the sulfur dioxide is reacted with a wet lime slurry to form the sulfite:

There is subsequent conversion, by oxidation, to the sulfate.

In the double alkali non-regenerative procedure, flue gas is scrubbed with a soluble alkali such as sodium sulfite which is subsequently regenerated with lime to form insoluble calcium sulfite:

After this, disposal of the calcium sulfite slurry occurs and the spent absorbent, sodium bisulfite, is regenerated by thermal means:

In all of these procedures, water exits the system as vapor in the flue gas.

In either the lime/limestone or sodium sulfite/lime scrubbing processes, the hydrated calcium sulfite and calcium sulfate can be of some environmental concern when the issue of disposal arises. This has, more than anything else, promoted efforts to develop alternate dry scrubbing procedures for the removal of sulfur dioxide. The dry systems have the additional advantage of reducing the pumping requirements that are necessary for the wet systems.

The tendency to advocate the use of dry lime scrubbing systems thereby produces a waste stream that can be handled by conventional fly ash removal procedures. There are also dry processes, such as the metal oxide processes, in which sulfur dioxide can be removed from gas streams by reaction with a metal oxide. These processes, which are able to operate at high temperatures (approximately 400°C; 750°F), are suitable for hot gas desulfurization without a cooling step. The metal oxides can usually be regenerated by aerial oxidation, to convert any metal sulfide(s) back to the oxide(s) or by use of a mixture of hydrogen and steam.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Removal of Nitrogen-Containing Gases

The occurrence of nitrogen in natural gas can be a major issue if the quantity is sufficient to lower the heating value. Several plants for the removal of nitrogen from the natural gas have been built, but it must be recognized that nitrogen removal requires liquefaction and fractionation of the entire gas stream which may affect process economics. In many cases, the nitrogen-containing natural gas is blended with a gas having a higher heating value and sold at a reduced price depending upon the thermal value (Btu/ft³).

Of equal interest is the occurrence of nitrogen compounds in gases produced by feedstock combustion. These compounds, the oxides, originate from the organically bound nitrogen in the coal:

Nitrogen oxides are formed during burning by oxidation, at the high temperatures, of the nitrogen in the fuel and in the air, giving rise to the terminology *thermal NOx* and *fuel NOx* as a means of distinguishing between the two sources of nitrogen oxides. Nitrogen oxides from whatever the sources are pollutants that must be removed from gas streams.

Many boilers are being built with burners designed to reduce nitrogen oxide formation by delaying fuel/air mixing, or distributed fuel addition, thereby establishing fuel-rich combustion zones within the burner whereby the reduced oxygen level maintains a low level of nitrogen oxides production. Other procedures employ ammonia to reduce the nitrogen oxides by injection of ammonia and oxygen into the post combustion zone:

Nitrogen compounds must be absorbed in several chemical and related processes, the most important of which is the absorption of nitrogen peroxide in water for the manufacture of nitric acid. Absorption of nitrous gases also takes place in the lead-chamber process used for the production of sulfuric acid, in the metallurgical industries where metals are treated with nitric acid, and in the purification of several tail gases.

It is also worth, at this point to give some consideration to the production of nitric acid from nitric oxide (using simple chemistry), as might be envisaged in the formation of nitrous and nitric acids in an industrial setting or even in the atmosphere; this latter phenomenon would result in the deposition of acid rain.

Thus, nitric oxide is oxidized to nitrogen peroxide:

Dimerization of nitrogen peroxide gives nitrogen tetroxide:

Combination of nitrogen peroxide and nitric oxide gives nitrogen trioxide:

In the presence of water vapor, nitrogen trioxide can be hydrated to nitrous acid:

In the liquid phase, the gross reaction equation of the formation of nitric acid is:

See also: Gas Cleaning, Gas Processing, Gas Treating.

Removal of Sulfur-Containing Gases

Historically, the first method for removing sulfur dioxide from flue gases consisted of water scrubbing the flue gas to absorb sulfur dioxide into solution, and the method was first used in London during the 1930s. Since then, various regulatory organizations in many countries have set standards for sulfur dioxide emissions which must be met.

Sulfur dioxide represents a high percentage of the sulfur oxide pollutants generated in combustion. The removal of the sulfur dioxide from the combustion gases before they are released to the stack is essential, and a considerable number of procedures exist for flue gas desulfurization (FGD). These procedures may be classified as wet or dry depending on whether a water mixture is used to absorb the sulfur dioxide or whether the acceptor is dry.

There are a variety of processes which are designed for sulfur dioxide removal from stack gas, but scrubbing process utilizing limestone (CaCO_3) or lime [$\text{Ca}(\text{OH})_2$] slurries have received more attention than other stack gas scrubbing processes. Attempts have been made to use dry limestone or dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$) within the combustor

as an in situ method for sulfur dioxide removal, thereby eliminating the wet sludge from wet processes. This involves injection of dry carbonate mineral with the coal followed by recovery of the calcined product along with sulfite and sulfate salts:

The majority of the stack gas scrubbing processes are designed to remove sulfur dioxide from the gas streams; some processes show the potential for removal of nitrogen oxide(s). However, there is the current line of thinking that pursues the options which enable sulfur oxides and nitrogen oxide(s) to be controlled, at least as far as possible, by modification of the combustion process. Sulfur (as already noted) can be removed by injecting limestone, with the coal into a boiler, while modifications of the combustion chamber, as well as methods of flame temperature regulation and techniques that lower combustion temperatures, such as injection of steam into the combustion region, are claimed to reduce emissions of nitrogen oxide(s).

The procedures can be classified further as regenerative or non-regenerative depending upon whether the chemical used to remove the sulfur dioxide can be regenerated and used again or whether the chemical passes to disposal.

In the wet regenerative processes, either elemental sulfur or sulfuric acid is recovered. In the wet non-regenerative lime and/or limestone procedures, a calcium sulfite or calcium sulfate sludge is produced that is disposed. Wet scrubbing processes contact the flue gas with a solution or slurry for sulfur dioxide removal.

In a wet limestone process, the flue gas contacts a limestone slurry in a scrubber:

Both the sulfite and the sulfate absorb water of hydration to form the sulfite/sulfate sludge.

In a wet lime process, a gas stream containing the sulfur dioxide is reacted with a wet lime slurry to form the sulfite:

There is subsequent conversion, by oxidation, to the sulfate.

In the double alkali non-regenerative procedure, flue gas is scrubbed with a soluble alkali such as sodium sulfite which is subsequently regenerated with lime to form insoluble calcium sulfite:

Disposal of the calcium sulfite slurry occurs, and the spent absorbent, sodium bisulfite, is regenerated by thermal means:

In all of these procedures, water exits the system as vapor in the flue gas.

In either the lime/limestone or sodium sulfite/lime scrubbing processes, the hydrated calcium sulfite and calcium sulfate can be of some environmental concern when the issue of disposal arises. This has, more than anything else, promoted efforts to develop alternate dry scrubbing procedures for the removal of sulfur dioxide. The dry systems have the additional advantage of reducing the pumping requirements necessary for the wet systems.

The tendency to advocate the use of dry lime scrubbing systems thereby produces a waste stream that can be handled by conventional fly ash removal procedures. There are also dry processes, such as the metal oxide processes, in which sulfur dioxide can be removed from gas streams by reaction with a metal oxide. These processes, which are able to operate at high temperatures (approximately 400°C; 750°F), are suitable for hot gas desulfurization without an energy-wasteful cooling step. The metal oxides can usually be regenerated by aerial oxidation, to convert any metal sulfide(s) back to the oxide(s) or by use of a mixture of hydrogen and steam.

The removal of carbonyl sulfide from gas streams, especially those that are destined for the manufacture of synthesis gas, has also been investigated using the principle of hydrogenation:

See also: Gas Cleaning, Gas Processing, Gas Treating.

Renewability

An energy resource is considered renewable if natural processes are constantly replenishing it. Wind, sunshine, geothermal heat, wave power, and wood are typical renewables. However, fossil fuels can also be renewable over many millions of years; some observers believe that geological processes are continually generating new crude oil, though not fast enough to refill oil fields as they are drawn down. Standard renewables, on the other hand, cannot be renewed perpetually because the Sun itself will not last forever. For these and other reasons, some scientists prefer to define renewability in terms of the ongoing human relationship to a given energy resource.

The renewability of a resource in terms of the rate at which humans exploit it compared to the rate at which nature renews it. On this view, there are many resources that are renewable under some conditions of use, but not all. If the resource is regenerated at a higher rate than it is used, it is considered renewable, but if it is exploited at a higher rate than it is regenerated, it is considered non-renewable. The renewability of an energy resource can change, therefore, depending on human activity. For example, wood used as fuel is currently a non-renewable resource wherever humans are logging forests more quickly than new timber is growing. However, if growth were to increase or cutting decrease, fuel wood would eventually become renewable again.

Renewability is a key parameter for evaluating energy technologies according to their environmental impact. The more renewable an energy resource is (that is, the faster it can be regenerated at the level it is being used), the less of an environmental impact it has. At present, coal is a non-renewable resource as it takes many millions of years for it to form. It is unlikely that the renewability of this resource is going to change due to coal's high level of exploitation by humans and its extremely slow rate of regeneration.

Wind electricity, however, has high renewability, as there is essentially no time lag between its use and regeneration. On these grounds alone, one would expect coal mining to have a greater environmental impact than wind generation. Exploitation of forests at rates low enough to permit renewal would likewise be expected to have less environmental impact than exploitation above renewal rates.

Coal and wind are extremes of low renewability and high renewability. It is of most interest to examine what energy technologies have intermediate renewability that can be realistically increased by policy choices. Renewability might be increased by more efficient use of a resource (e.g., wood), allowing lower harvesting rates. It might also, in a technical sense, be increased by discovering how to turn a non-resource renewable material into a useful resource.

See also: Renewable Energy.

Renewable Energy

Renewable energy is any form of energy obtained from natural resources, such as biomass, geothermal heat, ocean energy, and wind. However, there are many different types of energy. Kinetic energy is energy available in the motion of particles, and wind energy is one example of this. Potential energy is the energy available because of the position between particles, such as water stored in a dam, the energy in a coiled spring, and energy stored in molecules (gasoline). There are many examples of energy: mechanical, electrical, thermal, chemical, magnetic, nuclear, biological, tidal, and geothermal. Renewable energy denotes a clean, nontoxic energy source that cannot be exhausted. In fact, renewable energy is no longer a niche sector, promoted only by governments and environmentalists. Public concern about climate change and protection of the environment, coupled with depletion of fossil energy reserves and environmental issues are driving increasing rates of investment into research for clean and cost-effective forms of energy.

The primary renewable energy sources are the Sun, wind, biomass, tides, waves, and the heat of the Earth (geothermal). Solar energy is referred to as renewable and/or sustainable energy because it will be available as long as the Sun continues to shine. Estimates for the life of the main stage of the Sun are another 4 to 5 billion years. Wind energy is derived from the uneven heating of the surface of the Earth due to more heat input at the equator with the accompanying transfer of water by evaporation and rain. In this sense, rivers and dams for hydro-energy are stored solar energy. Another aspect of solar energy is the conversion of sunlight into biomass by photosynthesis. Animal products such as whale oil and biogas from manure are derived from this form of solar energy.

Tidal energy is primarily due to the gravitational interaction of the Earth and the moon. Another renewable energy is geothermal, due to heat from the Earth generated by decay of radioactive particles from when the solar system formed. Volcanoes are fiery examples of geothermal energy reaching the surface of the Earth from the hot and molten interior. Overall, a growing source of energy is biomass – primarily wood and charcoal, but also crop residue and even animal dung for cooking and some heating. This contributes to deforestation and the loss of topsoil in developing countries.

Fossil fuels are stored solar energy from past geological ages (i.e., ancient sunlight). Even though the quantities of oil, natural gas, and coal are large, they are finite and resources are sufficient to power the industrialized world anywhere from a few more decades to a few more centuries, depending on the resource. There are also large environmental costs associated with fossil fuel exploitation, from habitat loss and destruction due to strip mining and oil spills to global warming of the atmosphere largely caused by the combustion by-product of carbon dioxide.

The advantages of renewable energy are many: sustainability (cannot be depleted), ubiquity (found everywhere across the world in contrast to fossil fuels and minerals), and essentially nonpolluting and carbon-free. The disadvantages of renewable energy are variability, low density, and generally higher initial cost for conversion hardware. For different forms of renewable energy, other disadvantages or perceived problems are visual pollution, odor from biomass, perceived avian issues with wind plants, large land requirements for solar conversion, and brine from many geothermal sources.

Renewable Energy – Sources

Renewable energy, often referred to as clean energy, comes from natural sources or processes that are constantly replenished. Renewable energy sources include (alphabetically rather than by common use or preference) (i) biomass, (ii) geothermal energy, (iii) hydroelectric energy, (iv) ocean energy, (v) solar energy, and (vi) wind energy.

Renewable energy provides substantial benefits for the climate but, like fossil fuel energy, are not without some effects on the environment, some of which may be considered to be significant. The exact type and intensity of environmental impacts varies depending on the specific technology used, the geographic location, and a number of other factors. By understanding the current and potential environmental issues associated with each renewable energy source, steps can be taken to avoid or at least minimize these impacts as they become a larger portion of the supply of electrical energy.

Despite the environmental impacts, renewable energy technologies compare extremely favorably to fossil fuels, and remain a core part of the solution of climate change issues.

Biomass

Biomass is organic material that comes from plants and animals, and includes crops, waste wood, and trees. Sources of biomass for producing electricity are diverse, ranging from energy crops (like switchgrass), to agricultural waste, manure, forest products and waste, and urban waste. Both the type of feedstock and the manner in which it is developed and harvested significantly affect land use and life-cycle global warming emissions impacts of producing power from biomass.

When biomass is burned, the chemical energy is released as heat and can generate electricity with a steam turbine. Biomass power plants share some similarities with fossil fuel power plants: both involve the combustion of a feedstock to generate electricity. Thus, biomass plants raise similar, but not identical, concerns about air emissions and water use as fossil fuel plants. However, the feedstock of biomass plants can be sustainably produced, while fossil fuels are non-renewable.

Biomass is often mistakenly described as a clean, renewable fuel and a greener alternative to coal and other fossil fuels for producing electricity. However, many forms of biomass – especially from forests – produce higher carbon emissions than fossil fuels. There are also negative consequences for biodiversity. However, some forms of biomass energy could serve as a low-carbon option under the right circumstances. For example, sawdust and chips from sawmills that would otherwise quickly decompose and release carbon can be a low-carbon energy source.

Geothermal

Geothermal technology is a new take on a recognizable process—the coils at the back of your fridge are a mini heat pump, removing heat from the interior to keep foods fresh and cool. In a home, geothermal or geo-exchange pumps use the constant temperature of the earth (a few feet below the surface) to cool homes in summer and warm houses in winter and also to heat water.

The core of the Earth is a source of heat due to the slow decay of radioactive particles in rocks at the center of the planet. Drilling deep wells brings hot underground water to the surface as a hydrothermal resource, which is then pumped through a turbine to create electricity.

Hydroelectric Power

Hydropower relies on water – typically fast-moving water in a large river or rapidly descending water from a high point – and converts the force of the water into electricity by spinning the turbine blades of a generator.

However, large hydroelectric plants – and the accompanying mega-dams – divert and reduce natural water flows, thereby restricting access for animal and human populations that rely on rivers.

Ocean Energy

Tidal and wave energy is still in a developmental phase, but the ocean will always be ruled by the moon's gravity, which makes harnessing its power an attractive option. Some tidal energy approaches may harm wildlife, such as tidal barrages, which work much like dams and are located in an ocean bay or lagoon. Like tidal power, wave power relies on dam-like structures or ocean floor-anchored devices on or just below the surface of the water.

Solar Energy

Solar cells (or photovoltaic cells) are made from silicon or other materials that transform sunlight directly into electricity. Distributed solar systems generate electricity locally for homes and businesses, either through rooftop panels or community projects that power entire neighborhoods. Solar farms can generate power for thousands of homes, using mirrors to concentrate sunlight across acres of solar cells. Floating solar farms (sometimes referred to as floatovoltaics) can be an effective use of wastewater facilities and bodies of water that are not ecologically sensitive.

Solar energy systems don't produce air pollutants or greenhouse gases, and as long as they are responsibly sited, most solar panels have few environmental impacts beyond the manufacturing process.

Wind Energy

Wind energy (or wind power) describes the process by which wind is used to generate electricity. Wind turbines convert the kinetic energy in the wind into mechanical power.

In the process, the wind energy turns turbine blades, which feeds an electric generator and produces electricity through turbines which can be placed anywhere with high wind speeds, such as hilltops and open plains or even offshore in open water.

Renewable Natural Gas

Renewable natural gas is a biogas which has been upgraded to a quality similar to natural gas. A biogas is a gas obtained from biomass. By upgrading the quality to that of natural gas, it becomes possible to distribute the gas to customers via the existing gas grid, and burned within existing appliances. Renewable natural gas is also known as sustainable natural gas, and is a subset of synthetic natural gas or substitute natural gas (SNG).

Renewable natural gas can be produced economically, and distributed via the existing gas grid, making it an attractive means of supplying existing premises with renewable heat and renewable gas energy, while requiring no extra capital outlay of the customer. The existing gas network allows distribution of gas energy over vast distances at a minimal cost in energy. Existing networks would allow biogas to be sourced from remote markets that are rich in low-cost biomass (Russia or Scandinavia for example).

In terms of the present context, renewable natural gas can be manufactured through two main processes which are (i) anaerobic digestion of organic (normally moist) material or (ii) thermal gasification of organic (normally dry) material that has been mined from the landfill. In both cases, the gas from primary production has to be upgraded in a secondary step to produce gas that is suitable for injection into the gas grid.

Research Octane Method

The research octane method (ROM) is a test method for determining the knock rating, in terms octane numbers, of fuels for use in spark-ignition engines. The data from test method are used in conjunction with the data from the Motor Octane Test Method to determine the octane number.

The research octane method (ASTM D908) measures the octane number of a gasoline under relatively mild, low-speed operating conditions. The motor octane method (ASTM D357) measures the octane number of a gasoline under the load of high revolutions per minute and elevated temperature.

See also: Octane Number., Octane Rating.

Reserves

At some time during the exploration or development processes, certain resources may become reserves. Such a reclassification can arise as a result of improvements in recovery techniques which may either make the resource accessible or cause a lowering of the recovery costs and render winning of the resource an economical proposition. In addition, other uses may also be found for a commodity, and the increased demand may result in an increase in price. Alternatively, a large deposit may become exhausted and unable to produce any more of the resource, thus forcing production to focus on a lower-grade, high-recovery-cost resource. More specifically, the use of the term reserves as being descriptive of the resource is subject to much speculation and, in fact, is subject to word variations. For example, reserves are classed as proved, probable, possible, and potential (Table R-15).

Table R-15 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

Proved reserves are those reserves of the mineral that have been positively identified as recoverable with current technology. Probable reserves are those reserves of the mineral that are nearly certain but a slight doubt does exist. Possible reserves are those reserves where there is an even greater degree of uncertainty but there is some information.

Potential reserves are based upon geological information related to the types of sediments where such resources are likely to occur, and they are considered to represent an educated guess. Also, there are the so-called undiscovered reserves which are lacking specific data and are often subject to speculation – some observers would say that these types of reserves are a little more than figments of imagination! Thus, in reality, and in spite of the use of self-righteous wordsmithing, the proved reserves may be a small part of the total hypothetical and/or speculative amounts of a resource.

See also: Resources and Reserves

Residual Herbaceous Biomass

Residual herbaceous biomass (straw) is the main residual herbaceous material for energy application. As it is a residual product, its availability for energy purposes is driven by the cereals markets and does not have autonomous market behavior. In addition, farms consume significant quantities of straw internally – as bed material for livestock, grain drying, etc. Some straw is also chaffed and returned back to the field as soil ameliorator. The net straw yield per hectare for energy application also depends on the crop, the grain yield per hectare, climate and cultivation conditions, etc. Nevertheless, one can roughly estimate that the average straw yield per hectare is approximately 50 to 65% of the grain yield per hectare from cereals and oilseeds.

Similar to herbaceous crops, straw usually has lower moisture content than woody biomass. Conversely, it has a lower calorific value, bulk density, ash melting point and higher content of ash, and problematic inorganic component such as chlorine, potassium, and sulfur, which cause corrosion and pollution. The last two drawbacks can be relatively easily overcome by leaving straw on the field for a while. In such a way, rainfall provides a natural leaching process and separates a large part of the potassium and the chlorine. Alternatively, fresh straw can be directly shipped to the gasification plant, where it is washed by dedicated facilities at moderate temperatures (50 to 60°C; 120 to 140°F). Due to washing, the initially low moisture content of straw becomes higher in both cases, and hence a mandatory drying is applied afterwards. In both cases also, the content of corrosive components is reduced, but not completely taken out. In order to decrease handling costs, straw and dedicated herbaceous energy crops are usually baled before being shipped to the gasification plant. The weight and the size of bales depend on the baling equipment and on the requirements of the gasification plant.

There are many opportunities for producing fuel from agricultural crops and crop residues. Possible end products include ethanol, vegetable oil, and solid cellulosic fuels. Ethanol can be produced from any grain, root, fruit, or juice crop containing fermentable carbohydrates. It also can be made from crops, residues, or wood that contain cellulose or other long-chain carbohydrates which can be hydrolyzed to fermentable sugars.

Vegetable oils are produced from numerous oil seed crops. Some of these oils have been evaluated in other laboratories as substitutes for diesel fuel. While all vegetable oils have high energy content, most require some processing to assure safe use in internal combustion engines.

The simplest form of agricultural biomass energy use involves direct combustion of cellulosic crops or residues, such as hay, straw, or corn fodder, to heat space or produce steam. Such fuels are useful for heating farm buildings and small commercial buildings in rural areas and for drying crops. Ideally, energy crops should be produced on land not needed for food production. This use should not increase the erosion hazard or cause other environmental damage. On the other hand, a variety of crops can be grown specifically to provide sources of energy, and once established, a stand of perennial biomass/energy crop is expected to remain productive for a period of 6 years or more.

See also: Agricultural Residues, Agricultural Waste, Biomass.

Residual Woody Biomass

Residual wood is the material that is a refuse without objective value within a specific context; otherwise, it constitutes a material at the end of its usefulness. Thus, a number of woody materials can be included in the group of residues and waste: thinning and logging residues from forest industry (tops, branches and small size stems), demolition wood and railway sleepers, fiberboard residues, cutter shavings, and plywood residues. Residual woody material is believed to be a very promising bioenergy resource since it is available at much lower or negligible cost compared to wood logs and short-rotation forestry.

The availability of residual woody biomass depends on the primary wood yield and typically accounts for 25 to 45% of all harvested wood on average. The heterogeneous composition of the residual and waste woody biomass (content of moisture and impurities) may preclude using this type of biomass for biomass-to-liquids production. Preliminary treatment of the residual and waste woody biomass may be necessary, in order to make it appropriate for processing to liquid fuels.

A residual (waste) product can be defined as a material, which is a refuse without objective value within a specific context; otherwise, it constitutes a material at the end of its usefulness. Ensuing from this definition, a number of woody materials can be included in the group of residues and waste: thinning and logging residues from forest industry (tops, branches, and small-size stems), demolition wood and railway sleepers, fiberboard residues, cutter shavings, and plywood residues. Residual woody material is believed to be a very promising bioenergy resource since it is available at much lower or negligible cost compared to wood logs and short-rotation forestry.

Residues

See also: Agricultural Residues, Agricultural Waste, Residual Woody Biomass.

Resources and Reserves

Resources are those usable materials that occur naturally within the Earth and are often referred to as natural resources which are usually either (i) non-renewable or (ii) renewable (Table R-16).

The former category refers to those resources which are, as the name implies, those resources that are no longer available once the available resource at a site is exhausted. In general terms, the development of resources is usually concerned with the production or use of energy.

Table R-16 An example of the general categorization of natural resources.

Resource category	Type	Name
Non-renewable	Fossil	Natural gas
		Crude oil
		Heavy crude oil
		Extra heavy crude oil
		Tar sand bitumen
	Minerals (nuclear examples)	Coal
		Oil Shale
		Uranium
		Thorium
		Clay minerals
Fluorine minerals		
Silica		
Sulfur minerals		
Renewable*	Biomass	Wood
		Grasses
		Crops
		Algae
		Aquatic plants
	Geothermal	Natural steam
		Hot water
		Volcanic heat
	Oceans	Ocean heat
		Ocean current
		Wave energy
	Solar	Solar-thermal conversion
		Photochemical energy
		Photoelectric energy
		Stored solar heat
	Tidal	Tidal energy
	Wind	Electric energy

*Listed alphabetically and not in any order of popularity of preference.

These resources have been useful to humans in a variety of ways, either directly in the original form (such as coal) or indirectly after certain modification (such as crude oil products). At one time, the Earth was believed to have an inexhaustible supply of natural resources. But it is no longer realized that some resources (the fossil fuels, environmental issues notwithstanding) are unlimited or inexhaustible – some resources are renewable while others are not.

Humans have been exploiting major groups of resources (including non-fossil fuels resources) which have now been depleted to an irreparable extent (Jazib, 2018). Mineral resources, which are non-renewable and include the fossil fuels (natural gas, crude oil, and coal). The fossil fuel sources are carbonaceous resources which are formed from the fossilized remains of prehistoric organisms, and are also considered non-renewable. Fossil fuels currently account for the majority of the total energy consumption of the world, and this is projected to continue for the next several decades. On the other hand, natural renewable resources, such as wind and water, have been used throughout history, and until recently were a predominant energy source.

It is pertinent to consider the use of natural resources since the onset of the Industrial Revolution in the late 1700s, when the use of the natural resources of the Earth which has focused on the production of energy. Therefore, it is necessary to understand the relationships that exist between a natural resource, the commodity produced from that resource, and the environment which can be represented by a simple equation of progression from one to the other:

$$\text{Natural resource} \rightarrow \text{commodity} \rightarrow \text{environment}$$

Perturbations in one aspect of this equation typically usually cause perturbations in one, or both, of the other two. For example, the availability of many metals depends upon the quantity of energy used and the amount of environmental damage tolerated in the extraction of low-grade ores. Mining and processing of resources offer the world valuable commodities suitable for a variety of industrial and domestic uses as well as a variety of contaminants. In addition, production and use may also involve major environmental concerns, including disturbance of land, air pollution from dust and smelter emissions, and water pollution from disrupted aquifers. This problem is aggravated by the fact that the general trend in mining involves utilization of less rich ores, almost analogous to the acceptance by refineries of lower-quality crude oil such as heavy crude oil as well as extra heavy crude oil and tar sand bitumen (Table R-17).

Table R-17 Simplified descriptions of conventional crude oil, tight oil, heavy crude oil, extra heavy crude oil, and tar sand bitumen*.

Conventional Crude Oil Mobile in the reservoir; API gravity: >25° High-permeability reservoir Primary recovery Secondary recovery
Tight Oil Similar properties to the properties of conventional crude oil; API gravity: >25° Immobile in the reservoir Low-permeability reservoir Horizontal drilling into reservoir Fracturing (typically multi-fracturing) to release fluids/gases
Heavy Crude Oil More viscous than conventional crude oil; API gravity: 10-20° Mobile in the reservoir High-permeability reservoir Secondary recovery Tertiary recovery (enhanced oil recovery – EOR, e.g., steam stimulation)

(Continued)

Table R-17 Simplified descriptions of conventional crude oil, tight oil, heavy crude oil, extra heavy crude oil, and tar sand bitumen*. (Continued)

Extra Heavy Crude Oil Similar properties to the properties of tar sand bitumen; API gravity: <10° Mobile in the reservoir High-permeability reservoir Secondary recovery Tertiary recovery (enhanced oil recovery – EOR, e.g., steam stimulation)
Tar Sand Bitumen Immobile in the deposit; API gravity: <10° High-permeability reservoir Mining (often preceded by explosive fracturing) Steam-assisted gravity draining (SAGD) Solvent methods (VAPEX) Extreme heating methods Innovative methods**

*This list is not intended for use as a means of classification.

**Innovative methods exclude tertiary recovery methods and methods such as steam-assisted gravity drainage (SAGD) and vapor-assisted extraction (VAPEX) methods but do include variants or hybrids thereof.

However, before launching into a description of the various natural resources, it is necessary to understand how the reserves of these natural resources are defined. A resource is the entire commodity that exists in the sediments and strata, whereas the reserves represent that fraction of a commodity that can be recovered economically. On the other hand, reserves are that subgroup of a resource that has been discovered, has a known size, and can be extracted economically. Factors that affect whether or not reserves can be extracted economically include (i) the demand, (ii) market price, (iii) mining costs, transportation costs, (iv) new technologies that can extract the material at a lower price, (v) taxes, (vi) environmental laws, and (vii) government price controls. Understandably, the economic value of a resource can change with time as these factors change.

Thus, at some time in the future, certain resources may become reserves. Such a reclassification can arise as a result of improvements in recovery techniques which may either make the resource accessible or cause a lowering of the recovery costs and render winning of the resource an economical proposition. In addition, other uses may also be found for a commodity, and the increased demand may result in an increase in price. Alternatively, a large deposit may become exhausted and unable to produce any more of the resource, thus forcing production to focus on a lower-grade, high-recovery-cost resource. More specifically, the use of the term reserves as being descriptive of the resource is subject to much speculation and, in fact, is subject to word variations. For example, reserves are classed as proved, probable, possible, and potential (Table R-18).

Table R-18 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

Proved reserves are those reserves of the mineral that have been positively identified as recoverable with current technology. Probable reserves are those reserves of the mineral that are nearly certain but a slight doubt does exist. Possible reserves are those reserves where there is an even greater degree of uncertainty but there is some

information. Potential reserves are based upon geological information related to the types of sediments where such resources are likely to occur and they are considered to represent an educated guess. Also, there are the so-called undiscovered reserves which are lacking specific data and are often subject to speculation – some observers would say that these types of reserves are a little more than figments of imagination! Thus, in reality, and in spite of the use of self-righteous wordsmithing, the proved reserves may be a small part of the total hypothetical and/or speculative amounts of a resource.

Reverse Osmosis

The reverse osmosis process is, as the name implies, based on reversing the solvent flow that would normally be caused by osmosis through a semipermeable membrane, i.e., one which would pass solvent but retain solute. This is achieved by applying a sufficiently large pressure drop across the membrane so that flow occurs in a direction opposite to that expected for osmosis.

Using a brine solution, if a semipermeable membrane that will pass water but not salt is placed on one side of the membrane and pure water on the other side of the membrane, the pure water will flow through the membrane which will raise the liquid level in the left arm and thus the pressure on the left side of the membrane until an equilibrium is established. Equilibrium occurs when the additional pressure caused by the rising liquid level on the relevant side of the membrane is adequate to prevent any further flow of pure water through the membrane. The additional pressure (the osmotic pressure of the salt solution) is a consequence of the difference in chemical potential between the brine solution and pure water. On the other hand, a sufficiently long column of brine is used at the beginning of the process, and this column of water offsets the osmotic pressure of the brine solution; no flow of pure water in either direction will occur. The pressure differential across the barrier under these conditions is the osmotic pressure of the brine.

Thus, in order for the reverse to occur, the pressure gradient opposing the osmotic pressure must be greater than the osmotic pressure so that the flow of pure water will actually be from left to right through the membrane. The required pressure drop across the membrane is the sum of the pressure needed to overcome osmotic pressure to prevent reverse flow and the pressure drop required to get reasonable flow rates. This depends on the concentration of impurities in the water phase.

Reversible Chemical Reactions

Reversible chemical reactions can be extremely selective for the separation of materials on the basis of their chemical reactivity. An example is the removal of acid gases such as carbon dioxide or sulfur dioxide from a variety of gas streams. When the gas stream is scrubbed with an aqueous alkaline solution, the acid gases react with the solution to form soluble salts which stay dissolved in the liquid phase. The non-reactive components of the flue gas are not dissolved and continue on the chosen path. The separation factor between reactive and non-reactive components in the feed is theoretically infinite and in practice achieves values approaching 100. That is, one theoretical stage of separation will separate a 50:50 feed mixture into a 99% pure product mixture. There are many types of reversible chemical separations, one of the oldest being the separation of various organic molecules by extraction with sulfuric acid of different strengths.

The material used as the reactive separating agent can be used either as a solid or a liquid. If it is applied as a solid to form a solid product, the process is very similar to adsorption and ion exchange. In this case, the reagent is usually supported on a solid carrier to get high surface area. It is also frequently incorporated into a polymer resin in much the same way as the active sites in an ion exchange resin. However, it can also be used as a simple solid reagent where it is insoluble in the feed stream and forms a reaction product which is also insoluble in the treated product stream. When the chemical reagent is applied as a liquid or solution to form a product soluble in the reagent, the separation process is very similar to solvent extraction when treating a liquid, and absorption or scrubbing when treating a gas.

See also: Adsorption, Ion-exchange.

Rhizosphere

The rhizosphere is a dynamic region governed by complex interactions between plants and the organisms that are in close association with the root. The composition and pattern of root exudates affect microbial activity and population numbers, which in turn have an impact on the nematodes and microarthropods that share this environment. Beneficial or harmful relationships exist between rhizosphere organisms and plants, which ultimately affect root function and plant growth. In addition, the rhizosphere may include organisms that do not directly benefit or harm plants but clearly influence plant growth and productivity.

A better understanding of the soil–root and soil–seed interface is needed to manage microorganisms, increase plant growth, and reduce the impact of plant production, agriculture, and fuel discharge on the environment. The benefits of studying the rhizosphere include the use of plant growth-promoting organisms and the suppression of plant diseases and weeds using biocontrol agents. Rhizosphere organisms can also be used to enhance the formation of stable soil aggregates and as bioremediation agents of contaminated soils. With greater understanding of the ecology and biota in the rhizosphere, this zone of increased nutrients, biotic activity, and interactions can be manipulated to improve plant productivity and environmental quality.

See also: Soil.

Rice Straw

Agricultural crop residues such as straw are a valuable renewable biomass resource. Silica, alkali minerals, and other undesirable characteristics of these crop residues make certain parts of the straw more or less valuable as bioenergy feedstocks. The use of rice straw for producing materials, fuels, and chemicals has been limited in part by the cost of pretreating straw biomass to make it a suitable feedstock for bioenergy conversion.

Rice straw is one of the so-called cereal straws and contains a low concentration of lignin. Rice straw has a higher silica content (as high as 18% w/w in clean rice straw and 19 to 24% w/w including silica from field dust) than other cereal straws, which makes pulping somewhat more costly due to increased chemical recovery difficulties and costs.

Recent developments in pre-pulp cleaning and pulping techniques have yielded much higher precipitation of silica from the pulping waste (also called black liquor), making chemical recovery more viable, and thereby diminishing pulping costs. Researchers have also identified new uses for the recovered silica, which can be made into bricks, ceramic articles, and glassware, thus completing the recovery cycle.

The quantity of straw available for removal from a field is dependent upon the amount that must be left to insure long-term sustainable crop production.

Straw can be converted to ethanol fuel. Determining the volume of fuel that could be produced depends on both the quantities of available straw and the technology used to convert the straw to ethanol. The amount of straw available depends on how much is produced each year and how much can be recovered while maintaining soil fertility.

See also: Agricultural Residues, Agricultural Waste, Straw, Wheat Straw.

Rotary Kiln Incinerator

The rotary kiln incinerator has a primary chamber and a secondary chamber. The primary chamber consists of an inclined refractory-lined cylindrical tube. Movement of the cylinder on its axis facilitates movement of waste. In the primary chamber, there is conversion of solid fraction to gases, through volatilization, destructive distillation, and partial combustion reactions. The secondary chamber is necessary to complete gas-phase combustion reactions.

The clinker spills out at the end of the cylinder. A tall flue gas stack, fan, or steam jet supplies the needed draft. Ash drops through the grate, but many particles are carried along with the hot gases. The particles and any combustible gases may be combusted in an afterburner. To control air pollution, the combustion product gases are further treated with acid gas scrubbers to remove sulfuric acid and nitric acid emissions, and then routed through bag houses to remove particulates before the gases are released into the atmosphere.

See also: Combustion, Incinerators.

Rotation

Rotation (sequencing) is the period of years between the establishment of a stand of timber and the time when it is considered ready for final harvest and regeneration.

Crop rotation (crop sequencing) is the practice of growing a series of dissimilar types of crops in the same area in sequential seasons for various benefits such as to avoid the buildup of pathogens and pests that often occurs when one species is continuously cropped. Crop rotation also seeks to balance the fertility demands of various crops to avoid excessive depletion of soil nutrients.

It also means that the succeeding crop belongs to a different family than the previous one. The planned rotation may vary from 2 or 3 years or a longer period.

As in the production of crops for agricultural use, the production of crops as sources of biofuels, rotation will also be necessary to ensure the replenishment of the soil and the growth of useful biomass.

Crops are selected that produce sufficient quantities of biomass at the appropriate time to reduce erosion by water or wind to within acceptable soil loss levels. The amount of biomass needed shall be determined using prediction technology.

See also: Crops, Energy From Crops.

Round Wood Products

Round wood products are logs and other round timber generated from harvesting trees for industrial or consumer use.

While there are primary use (usually poles, posts, piles) for round wood products, forest-based woody biomass includes round wood products and logging residue and can also be used as biomass for a biomass-to-energy plant.

See also: Residual Woody Biomass, Wood Biomass.

RTP Process

The RTP process (rapid thermal processing) involves rapid heating of biomass in the absence of oxygen. The biomass is vaporized and then rapidly cooled to generate high yields of pyrolysis oil (Table R-19). The process utilizes a circulating transported fluidized bed reactor system similar to that used in the fluid catalytic cracking technology. The pyrolysis oil can then be burned for energy in industrial burners and furnaces for heat or used to generate electricity.

Table R-19 Yields and quality of pyrolysis oil from various feedstocks.

Biomass	Yield, % w/w	Heating value, Btu/lb
Hardwood	70-75	7,400–8,200
Softwood	70-80	7,300–8,000
Hardwood Bark	60-65	7,180–8,680
Softwood Bark	55-65	7,180–8,500
Corn Fiber	65-75	7,570–8,680
Bagasse	70-75	8,100–8,200
Waste Paper	60-80	7,300–7,400

The pyrolysis oil has virtually no sulfur and can be adapted for use in a wide variety of industries including electrical generation, forestry, refining and petrochemicals, pulp and paper, and the most energy-intensive heavy industry.

In addition to pyrolysis oil, the process also produces char and a non-condensable gas, both of which can be used to provide process energy in the reheater to maintain the process and/or in the dryer to condition the biomass.

Saponification Value

The saponification value (SV, or saponification number, SN) represents the number of milligrams of potassium hydroxide (KOH) required to saponify one gram of fat under the conditions specified in the test method. The value is a measure of the average molecular weight (or chain length) of all of the fatty acids present in the sample as triglycerides. The higher the saponification value, the lower the fatty acids average length, the lower the mean molecular weight of triglycerides and the converse is also true – i.e., the lower the saponification value, the higher the average length of the fatty acids present in the sample as triglycerides.

To determine saponification value, the sample is hot-saponified with an excess of alkali (usually potassium hydroxide dissolved in ethanol), in standard conditions, generally for half an hour under reflux. Alkali is mainly consumed by glycerides (monoglycerides, diglycerides) and triglycerides as well as by free fatty acids and other ester-type components such as lactones. At the end of the reaction, the remaining quantity of alkali is titrated against the standard solution of hydrochloric acid (HCl). The saponification value (SV, mg KOH/ g of sample) is calculated by the following equation:

$$SV = [(B-S) \times M \times 56.1]/W$$

In the equation, (B-S) is the difference between the volume of HCl solution used for the blank run and for the tested sample, in mL, M is the molarity of HCl solution, in mol L⁻¹, 56.1 is the molecular weight of KOH, in g mol⁻¹, and W is the weight of sample, in g.

Sasol Slurry Phase Reactor

The Sasol slurry phase reactor uses a slurry bubble column (and sometimes referred to as a bubble phase reactor) was a development to convert coal to liquid products using the Fischer-Tropsch process. The reactor is essentially a vessel containing a slurry comprising catalyst dispersed in the wax produced by the Fischer-Tropsch synthesis.

In the process, synthesis gas is bubbled through this slurry and is converted to hydrocarbons. The heat generated is transferred from the slurry to the cooling coils inside the reactor to generate steam. The low-boiling hydrocarbon derivatives in the vapor phase are removed from the freeboard at the top of the SPR together with the unconverted reactants before being condensed in the downstream cooling train. The higher-boiling liquid hydrocarbon derivatives are part of the slurry from which they must be removed by means of a solid separation process. The successful development of an effective and relatively cheap liquid–solid separation step is crucial to the development of the slurry phase reactor, and the catalyst is sufficiently strong to prevent excessive attrition.

A characteristic of the slurry phase reactor is that the liquid phase is well mixed and can operate virtually isothermally. The absence of axial and radial temperature gradients, as is the case in a fixed-bed reactor, allows for much higher average operating temperatures in the slurry phase reactor and therefore higher reaction rates. In addition, a highly active catalyst can be accommodated, since the limitations of intra-particle diffusion are avoided by applying relatively small size (20–300 µm) of the catalyst particles sizes without adverse pressure drop consequences.

The slurry phase reactor allows for on-line catalyst withdrawal and addition, which is not feasible with a fixed bed reactor. This is especially important for iron-catalyzed Fischer-Tropsch synthesis where the catalyst must be replaced periodically. In the case of non-iron catalysts, this is of lesser importance, but the addition and withdrawal features can also be used in combination with regeneration or rejuvenation of a cobalt-based catalyst outside the reactor when reactivation of the catalyst inventory is required.

Sawdust Briquettes

Briquettes produced from biomass residues and from agricultural residues are a good substitute for firewood. Also, the formation of briquettes at the very site of its production stops air pollution to a large extent. Hence briquetting of sawdust produces a renewable and environmentally friendly source of energy.

Sawdust is waste material from all types of primary and secondary wood processing. Between 10 and 13% of a log is reduced to sawdust in milling operations. Sawdust is bulky, and is therefore expensive to store and transport. Also, the calorific value of sawdust is quite low, so that briquetting is an ideal way to reduce the bulk, to increase the density, and thus to increase the calorific value. The equipment required for producing sawdust briquettes consist of a drier, a press, and an extruder with a tapered screw and a large revolving disk.

Sawdust briquettes are formed under sufficiently high pressure to produce cohesion between wood particles. In the process, the lignin softens and binds the briquette, so no additional binder is required. The use of sawdust briquettes has several advantages, including (i) the price which is usually approximately the same as fuel wood but is much more convenient to use as they do not require further cutting and chopping, (ii) the good burning characteristics in any kind of solid fuel stove and boiler, (iii) the quick ignition followed by clean burning and only leaving 1 to 6% w/w ash, (iv) the sulfur-free feedstock which burns without producing an odor, and (v) a high heat content.

SCOT Process

The SCOT process (Shell Claus off-gas treating process) is a tail gas treating process that was developed in the early 1970s and consists of a combination of a catalytic hydrogenation/hydrolysis step and an amine scrubbing unit. The hydrogenation/hydrolysis of the sulfur compounds in the tail gases from the Claus unit has already been covered above.

The early SCOT units consisted of a hydrogenation/hydrolysis reactor and a conventional amine unit. The Claus tail gas, after being reduced in the reactor, is cooled in a quench column and scrubbed by a Sulfinol solution. The clean tail gas goes to a Claus incinerator and the acid gas-rich solution is regenerated in a stripping column. The acid gas off the top of the stripper is recycled back to the Claus plant for further conversion of the hydrogen sulfide. The absorber is operated at near atmospheric pressure, and the amine solvent is not highly loaded with acid gases. Because the solution is not highly loaded, unlike high pressure operation, there is no need for an intermediate flash vessel and the loaded solution goes directly to a stripper.

Early SCOT units used diisopropanolamine in the Sulfinol (Sulfinol-D) solution. Methyl diethanolamine-based Sulfinol (Sulfinol-M) was used later to enhance hydrogen sulfide removal and to allow for selective rejection of carbon dioxide in the absorber.

To achieve the lowest possible hydrogen sulfide content in the treated gas, the Super-SCOT configuration was introduced. In this version, the loaded Sulfinol-M solution is regenerated in two stages. The partially stripped solvent goes to the middle of the absorber, while the fully stripped solvent goes to the top of the absorber. The solvent going to the top of the absorber is cooled below that used in the conventional SCOT process.

The SCOT process can be configured in various ways. For example, it can be integrated with the upstream acid gas removal unit if the same solvent is used in both units. Another configuration has been used to cascade the upstream gas clean-up with the SCOT unit. A hydrogen sulfide-lean acid gas from the upstream gas treating unit is sent to a SCOT process with two absorbers. In the first absorber, the hydrogen sulfide-lean acid gas is enriched, while the second absorber treats the Claus tail gas. A common stripper is used for both SCOT absorbers, and, in this latter configuration, different solvents could be used in both the upstream and the SCOT units.

The SCOT process is adversely affected by high concentrations of carbon dioxide, and since gaseous emissions from oil shale processing are expected to be rich in carbon dioxide, higher rates of recycling, more complete fuel combustion, and perhaps steam injection to dissolve the carbon dioxide may be necessary.

Scrap Tires

Tire recycling has become a necessity because of the huge piles of tires that represent a threat to the environment. The used tires represent a source of energy and valuable chemical products. By thermal decomposition of rubber under reduced pressure, it is possible to recover the useful compounds.

To alleviate the problems caused by scrap tire stockpiles, it is essential to adopt appropriate waste management strategy to cope with the increasing amount of scrap tires generated every year. Major ways of utilizing scrap tires, including retreading, recycling (in civil engineering and ground rubber applications), and energy recovery (e.g., through combustion in cement kilns and pyrolysis). The most important methods for sustainable environmental stewardship is converting the tires to bio-oil.

Thermochemical conversion processes are an approach to producing liquids and chemicals from scrap tires. These processes include incineration, hydrothermal liquefaction (HTL), gasification, and pyrolysis that can also be completed in the presence or absence of catalysts.

In the case of gasification – a thermochemical process that converts organic material to a gas mixture (synthesis gas) as well as minor products such as water and char at elevated temperature (800 to 1,000°C, 1,470 to 1,830°F) and partial pressure. Gasification at high temperature and a controlled environment results in converting a great proportion of the biomass into gas products. Gas products mainly include methane, ethane, hydrogen, carbon monoxide, carbon dioxide, and char in addition to a small amount of tar. The synthesis gas is predominantly used in gas turbines and engines to produce electricity.

Gasification reactors come in various styles such as fixed bed, fluidized bed, and entrained bed reactors.

Screening

Screening is the separation of a mixture of various grain sizes into two narrower size range fractions by means of a surface containing holes of a uniform size which are typically square, but other shapes of holes, particularly rectangular, are also used. The screen surface can consist of woven wire, silk or plastic cloth, perforated or punched plate, grizzly bars, or wedge wire sections. Part of the feed consisting of small enough particles can pass through the holes, and the remainder of the feedstock – consisting of larger particles – is retained on the screen surface.

However, while screening or sieving separates a mixture of solid particles according to size, the process is not always precise because the particle shape affects the size of a particle which will pass through a given size hole. Most screening operations require a size reduction operation such as crushing, grinding, or milling which produces a mixture of particulate materials that vary in size, shape, density, and abrasive properties. An initial step for such a mixture is a sieve analysis to determine the amount of the mixture that falls into the various size fractions that are relevant to the screening process.

The material passing through the screen is the *undersize* or *minus material* for the particular screen size, while the material retained on the screen is the *oversize* or *plus material*. The size distribution can be determined for the original feedstock by using a series of screens of successively smaller-sized holes. In the process, the feedstock is initially fed onto the screen having the largest holes, the undersize goes to the screen with the next largest hole size, and so on until the feed has passed through the entire series of screens. The oversize on each screen and the undersize from the smallest and final screen are weighed and reported as percentage of original feed versus screen hole size or mesh.

A standard test method (the sieve analysis test method) has been developed to determine size distributions of solid materials, and the results of the test are used to follow the effectiveness of operation of screening devices as well as the effectiveness of crushing and grinding equipment. The method uses a series of standard metal mesh sieves arranged vertically in order of increasing mesh or number of wires per inch (decreasing hole size) from top to bottom. The stack of sieves is clamped into a shaker, the feed is introduced into the top sieve, and the stack is shaken for a standardized time and intensity. The amounts left on each sieve and the final undersize are weighed and reported as percent of the feedstock.

Full-size screening operations can be used in much the same way as the above sieve analysis to fractionate a mixed feed into a group of relatively uniform-sized fractions by passing the feedstock across a series of screens having

decreasing size holes, and the oversize and undersize can be collected as desired. The full-size screens are shaken in a reciprocating, rotary, or vibrating motion as the feed passes over the screen surface, thereby providing provide a high efficiency process.

Scrubbers

Scrubber systems are a diverse group of air pollution control devices that can be used to remove particulate matter and/or gases from industrial exhaust streams. Traditionally, the term *scrubber* has referred to pollution control devices that use liquid to wash unwanted pollutants from a gas stream. Recently, the term is also used to describe systems that inject a dry reagent or slurry into a dirty exhaust stream to remove acid gases. Scrubbers are one of the primary devices that control gaseous emissions, especially acid gases. Scrubbers can also be used for heat recovery from hot gases by flue gas condensation.

A dry or semi-dry scrubbing system does not involve the use of moisture and dry scrubbers do generally not have a stack steam plume or wastewater handling/disposal requirements. Dry scrubbing systems are used to remove acid gases primarily from combustion sources.

Dry scrubbing systems can be categorized as dry sorbent injectors or as spray dryer absorbers, which are also called semi-dry scrubbers or spray dryers. Dry scrubbing systems are often used for the removal of odorous and corrosive gases from wastewater treatment plant operations. The media used is typically an activated alumina compound impregnated with materials to handle specific gases such as hydrogen sulfide.

Wet scrubbers use water to remove dust entrained in gas streams. In a wet scrubber, the polluted gas stream is brought into contact with the scrubbing liquid, by spraying it with the liquid, by forcing it through a pool of liquid, or by some other contact method, so as to remove the pollutants.

Many different types of devices are available for wet scrubbing, including spray chambers, wet cyclones, mechanical scrubbers, orifice scrubbers, venture scrubbers, and packed towers. High-energy venturi scrubbers are probably the only type that has sufficiently high removal efficiencies to satisfy emissions standards. Efficiencies between 93.6 and 99.8% have been achieved for particles smaller than 5 microns, but these efficiencies entail high pressure losses and constant gas flow rates.

Scrubbers can be designed to collect particulate matter and/or gaseous pollutants. Wet scrubbers remove dust particles by capturing them in liquid droplets. Wet scrubbers remove pollutant gases by dissolving or absorbing them into the liquid. Any droplets that are in the scrubber inlet gas must be separated from the outlet gas stream by means of another device referred to as a mist eliminator. Also, the resultant scrubbing liquid must be treated prior to any ultimate discharge or being reused in the plant.

Scrubbing

Scrubbing is a process for removing contaminants from gas streams using systems (such as chemical scrubbers, gas scrubbers) and are a diverse group of control devices that can be used to remove gases and particulate matter from gas streams. Traditionally, the term “scrubber” has referred to pollution control devices that use liquid to wash unwanted pollutants from a gas stream. Scrubbing is one of the primary processes that control gaseous emissions, especially acid gases. Scrubbers can also be used for heat recovery from hot gases by flue gas condensation.

Scrubbers can be divided into three types: (i) packed bed scrubbers, (ii) low energy scrubbers, and (iii) high energy scrubbers.

Packed bed scrubbers include countercurrent packed towers and cross-flow beds containing packings of fiber, rings, saddles, or other commercial packing materials for gas-liquid contacting. They are useful for collecting mists and soluble solids as well as absorbing gases. The low energy scrubbers include spray scrubbers, baffle- and centrifugal-type scrubbers, self-induced spray scrubbers, and some mechanically aided scrubbers. High energy scrubbers generally plate towers and many gas-atomized spray units. These latter units are venturi units or cocurrent mixers such as orifice plates or structured in-line packings. The high gas velocity relative

to the liquid in the venturi and cocurrent mixers atomizes the liquid, while the high turbulence promotes contacting of the phases. Venturi units are used mostly for dust collection only and can capture fine particles. However, they usually require a cyclone separator to remove the liquid from the treated gas and may even need further mist eliminating devices.

More specifically, a wet scrubber is used for cleaning (pollutant removal, including removal of dust particles) a gas stream. Wet scrubbing works via the contact of target compounds or particulate matter with the scrubbing solution which may be water (for dust removal) or solutions of reagents that specifically target certain compounds. Process exhaust gas can also contain water-soluble toxic and/or corrosive gases such as hydrogen chloride (HCl) or ammonia (NH_3) which can be removed by use of a wet scrubber. The removal efficiency of pollutants is improved by increasing residence time in the scrubber or by the increase of surface area of the scrubber solution by the use of a spray nozzle, packed towers, or an aspirator. However, use of a wet scrubber may increase the proportion of water in the gas, resulting in a visible stack plume, if the gas is sent to a stack. Almost all wet scrubbers involve two distinct zones of operation. In the first zone, the particles are captured and solutes are dissolved from the gas phase into the liquid. In the second zone, the liquid containing the particles and dissolved solute is removed from the gas.

A dry or semi-dry scrubbing system, unlike the wet scrubber, does not saturate the flue gas stream that is being treated with moisture. In some cases, no moisture is added, while in others, only the amount of moisture that can be evaporated in the flue gas without condensing is added. Therefore, dry scrubbers generally do not have a stack steam plume or wastewater handling/disposal requirements. Dry scrubbing systems are used to remove acid gases (such as sulfur dioxide, SO_2 and hydrogen chloride, HCl) primarily from combustion sources.

There are a number of dry type scrubbing system designs, but all consist of two main sections or devices: a device to introduce the acid gas sorbent material into the gas stream and a particulate matter control device to remove reaction products, excess sorbent material as well as any particulate matter already in the flue gas. Dry scrubbing systems can be categorized as dry sorbent injectors (DSIs) or as spray dryer adsorbers (SDAs, also called semi-dry scrubbers or spray dryers).

Dry sorbent injection involves the addition of an alkaline material [usually hydrated lime, $\text{Ca}(\text{OH})_2$, sodium carbonate, Na_2CO_3 , or sodium bicarbonate, NaHCO_3] into the gas stream to react with the acid gases. The acid gases react with the alkaline sorbents to form solid salts which are removed in the particulate control device.

In spray dryer absorbers, the flue gases are introduced into an absorbing tower (dryer) where the gases are contacted with a finely atomized alkaline slurry. Acid gases are absorbed by the slurry mixture and react to form solid salts which are removed by the particulate control device. The heat of the flue gas is used to evaporate all the water droplets, leaving a non-saturated flue gas to exit the absorber tower. Spray dryers are capable of achieving high (>80%) acid gas removal efficiencies.

See also: Gas Cleaning, Gas Processing, Gas Treating, Stripping.

Scrubbing Reagent

Alkaline sorbents are used for scrubbing flue gases to remove sulfur dioxide. Depending on the application, the two most important are lime and sodium hydroxide (caustic soda). Lime is typically used on large coal or oil-fired boilers as found in power plants, as it is very much less expensive than caustic soda. This results in the slurry being circulated through the scrubber instead of a solution and equipment performance can suffer.

A spray tower is typically used for this application. The use of lime results in a slurry of calcium sulfite (CaSO_3) that must be disposed of. Fortunately, calcium sulfite can be oxidized to produce the by-product gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) which is marketable for use in the building products industry.

Caustic soda is limited to smaller combustion units because it is more expensive than lime, but it has the advantage that it forms a solution rather than a slurry. This makes it easier to operate. It produces a solution of sodium sulfite/bisulfite (depending on the pH), or sodium sulfate that must be sent to disposal.

It is possible to remove sulfur dioxide by using a cold solution of sodium sulfite, which forms a sodium hydrogen sulfite solution. By heating this solution, the reaction can be reversed to form sulfur dioxide and the sodium sulfite solution. In theory, the sodium sulfite does not undergo a chemical change during the extraction from water to another phase. While a chemical change does occur during the extraction of the sulfur dioxide from the gas mixture,

it is the case that the extraction equilibrium is shifted by changing the temperature rather than by the use of a chemical reagent.

Seashore Mallow

Many land areas are presently not arable because freshwater is lacking, the soils are naturally saline, or the soils are salty as the result of previous agricultural practices. Many of these areas have abundant saline water available either as surface or ground water. Seashore mallow is a novel salt-tolerant perennial crop, derived from a salt marsh plant. With an oil content of approximately 18% w/w and residual meal that contains 30% w/w protein, this crop can be grown on saline land and produce vegetable oil on underutilized or non-arable land.

Seashore mallow has a productive life of approximately ten years, and the oil is similar in fatty acid composition to the oil from cottonseed. There are few reported insects or diseases that impact the crop; breeding efforts have been almost non-existent. Due to limited breeding efforts, the yields of seashore mallow are low compared to other oilseeds. Researchers envision at least four ways that the seashore mallow may fit into agronomic scenarios: (i) grown on salinized farmland, (ii) grown on dry farmland with brackish water wells, (iii) grown on sandy coastal deserts, or (iv) grown on farmland or aquatic ecosystems in transition.

Secondary Biomass Feedstocks

Biomass is a renewable energy source derived from living, or recently living organisms, such as wood, waste, and alcohol fuels. For example, forest residues (such as dead trees, branches, and tree stumps), yard clippings and wood chips, and garbage may be used as biomass.

Secondary biomass feedstocks differ from primary biomass feedstocks in that the secondary feedstocks are a by-product of processing of the primary feedstocks. By processing, it is meant that there is substantial physical or chemical breakdown of the primary biomass and production of by-products; processors may be factories or animals. Field processes such as harvesting, bundling, chipping, or pressing do not cause a biomass resource that was produced by photosynthesis (e.g., tree tops and limbs) to be classified as secondary biomass.

Specific examples of secondary biomass include sawdust from sawmills, black liquor (which is a by-product of paper making), and cheese whey (which is a by-product of cheese making processes). Manure from concentrated animal feeding operations is collectable secondary biomass resources. Vegetable oils used for biodiesel that are derived directly from the processing of oilseeds for various uses are also a secondary biomass resource.

Residues and by-product streams from food, feed, fiber, wood, and materials processing plants are the main source of secondary biomass. Secondary biomass feedstocks differ from primary biomass feedstocks in that the secondary feedstocks are a by-product of processing of the primary feedstocks.

By processing, it is meant that there is substantial physical or chemical breakdown of the primary biomass and production of by-products. Processors may be factories or animals. Field processes such as harvesting, bundling, chipping, or pressing do not cause a biomass resource that was produced by photosynthesis (e.g., tree tops and limbs) to be classified as secondary biomass.

See also: Biomass, Primary Biomass.

Secondary Gasification

Secondary gasification typically involves the gasification of char from the primary gasifier. This is usually accomplished by reacting the hot char with water vapor to produce carbon monoxide and hydrogen:

See also: Biomass Gasification, Gasification.

Sedimentation

Sedimentation is a physical process where particles suspended in a liquid are forced to settle by a combination of gravity and inertial forces on both the solid particles and the liquid carrier. In order to achieve sedimentation, the net forces on a particle in the desired direction of settling must be greater than the forces tending to move the particle in the opposite direction. This net force causes the particle to move in the desired direction which would be upward for low density particles which float in water, or downward for high density particles such as the metal hydroxides and sulfides.

In the current context, sedimentation is the tendency for chemicals in suspension in water to settle out of the water and come to rest against a barrier. In geology, sedimentation is often used as the opposite of erosion, i.e., the terminal end of sediment transport. Settling is the falling of suspended particles through the liquid, whereas sedimentation is the termination of the settling process. Sedimentation may pertain to objects of various sizes, ranging from large rocks in flowing water to suspensions of dust which produce significant sedimentation. The term is typically used in geology to describe the deposition of sediment which results in the formation of sedimentary rock.

Sedimentation can be achieved in either batch or continuous equipment. However, continuous equipment is much more common, especially where large volumes of wastewater are to be treated. In recent years, a number of manufacturers have developed compact, continuous units for the entire pretreatment of wastewater. These units provide first chemical precipitation and pH adjustment and then sedimentation and clarification of the resulting slurry.

Sedimentation can be generally classified into three different types that are all applicable to chemicals. Type 1 sedimentation is characterized by particles that settle discretely at a constant settling velocity, and typically, these particles settle as individual particles and do not flocculate or stick to other during settling. Type 2 sedimentation is characterized by particles that flocculate during sedimentation, and because of this, the particle size is constantly changing, and therefore their settling velocity is changing. Type 3 sedimentation (also known as zone sedimentation) involves particles that are at a high concentration (for example, greater than 1,000 mg/L) such that the particles tend to settle as a mass and a distinct clear zone and sludge zone are present. Zone settling occurs in active sludge sedimentation and sedimentation of sludge thickeners.

In terms of the sedimentation of chemicals, some of the chemicals may be adsorbed on the suspended material (especially if the suspended material is clay or another highly adsorptive mineral) and deposited to the bottom. This mainly happens in shallow waters where particulate matter is abundant and water is subjected to intense mixing, usually through turbulence. Simultaneously, the process of biosedimentation can also occur when plankton and other organisms absorb the chemical. The suspended forms of the chemicals undergo intense chemical and biological (microbial) decomposition in the water. However, this situation radically changes when the suspended chemical reaches the lake bed, river bed, or sea bed and the decomposition rate of the chemical(s) buried on the bottom abruptly drops. The oxidation processes slow down, especially under anaerobic conditions in the bottom environment, and the chemical(s) accumulated inside the sediments can be preserved for many months and even years.

Flocculation and coagulation agents are commonly used in conjunction with sedimentation in aqueous systems to improve the separation of the precipitated solids (or sludge) from the aqueous phase. Coagulation is the collection or aggregation of small colloidal particles of precipitate to form larger aggregate particles. Coagulation is enhanced by the addition of strongly ionic chemicals such as acids, lime, alum, or ferrous sulfate in a region of intense mixing. Flocculation is the further growth of the coagulated aggregates by their coalescence as the aggregates contact one another. Flocculation is a slower process than coagulation but produces larger, more easily settled particles.

See also: Chemical Precipitation, Coagulation, Flocculation.

Sedimentary Strata

By definition, a rock is any naturally formed, nonliving, coherent aggregate mass of solid matter that constitutes part of a planet, asteroid, moon, or other planetary object. There are three families of rocks: (i) igneous rocks, which are formed from the cooling and consolidation of magma or lava, (ii) sedimentary rocks, which are formed from either chemical precipitation of material or deposition of particles transported in suspension, and (iii) metamorphic rocks,

which are formed from changing a rock as a result of high temperatures, high pressures, or both. It is the second of the three types of rock to which this section is devoted.

The sedimentary rock is typically from as a stratum (or layer) that was deposited over time because of a physical or chemical effect that caused the rock to form particles that then deposited in the layer. A sequence of strata (pl: layers) deposited without interruption is said to be *conformable*, but if there are breaks in the strata that represent times of non-deposition or erosion, the term to be applied is *unconformity*.

Stratification is the layering that occurs in most sedimentary rocks and at the surface of the Earth, typically from fragmental deposits. The layers can range from fractions of an inch to several feet (or even to several yards) in thickness and vary in shape. The strata may range from thin sheets that cover many square miles to thick lens-like bodies that extend (laterally) only a few feet.

Stratigraphy is the branch of geology that focuses on the study of strata (rock layers) and layering (stratification). Stratigraphy has two related subfields: (i) lithostratigraphy (lithologic stratigraphy) and biostratigraphy (biologic stratigraphy). The former (lithostratigraphy) focuses on the variation in rock units, most obviously displayed as visible layering, due to physical contrasts in rock type (lithology) which can occur vertically as layering (bedding), or laterally, and reflects changes in the environments of the deposition (facies change). These variations provide a lithostratigraphy or lithologic stratigraphy of the rock unit.

See also: Sedimentation.

Selectox Process

Liquid redox sulfur recovery processes are liquid-phase oxidation processes which use a dilute aqueous solution of iron or vanadium to remove hydrogen sulfide selectively by chemical absorption from sour gas streams. These processes can be used on relatively small or dilute hydrogen sulfide stream to recover sulfur from the acid gas stream, or, in some cases, they can be used in place of an acid gas removal process. The mildly alkaline lean liquid scrubs the hydrogen sulfide from the inlet gas stream, and the catalyst oxidizes the hydrogen sulfide to elemental sulfur. The reduced catalyst is regenerated by contact with air in the oxidizer(s). Sulfur is removed from the solution by flotation or settling, depending on the process.

The *Selectox process* is based on replacing the Claus first stage thermal reactor (the furnace) with a catalytic oxidation step. A catalytic oxidation reactor can operate at much lower temperatures than the furnace and maintain a more stable flame temperature with lean hydrogen sulfide feeds.

Two versions of the process are offered. The first option is a once-through option, treating acid gases with up to 5% hydrogen sulfide and in which sulfur recovery is on the order of 84 to 94% w/w for hydrogen sulfide in the feed gas of 2 to 5% v/v, respectively. In the second option, which is a recycle version that handles hydrogen sulfide concentrations on the order of 5 to 100% v/v, the gas is recycled from the Selectox reactor condenser to cool the reactor outlet temperature not to exceed 370°C (700°F). The temperature limit is set so that carbon steel can be used for the reactor vessel.

The recycle Selectox process is an all-catalytic process in which there are no flames at any point in the process. A special catalyst bed replaces the acid gas burner in a conventional Claus plant, and the catalyst occupies the top few inches of the first bed, where it promotes the selective oxidation of hydrogen sulfide to sulfur dioxide. The remainder of the bed is filled with Claus catalyst where the Claus reaction occurs to approximately 80% completion. The highly exothermic nature of these reactions requires that the feed gas be monitored for the concentration of hydrogen sulfide to avoid overheating.

Approximately 80% v/v of the hydrogen sulfide is converted to sulfur in the Selectox reactor. The reactions are of the typical Claus type: the first reaction is the conversion of hydrogen sulfide to sulfur dioxide as the predominant reaction, then the hydrogen sulfide reacts with the sulfur dioxide to form elemental sulfur. The rest of the sulfur is recovered in conventional Claus stages. Up to 98% w/w sulfur recovery efficiency can be achieved for a 50% hydrogen sulfide acid gas feed to the recycle version of the Selectox process. Higher sulfur recoveries can only be had with tail gas treating, such as the BSR/Selectox process.

In the BSR/Selectox tail gas process, the gases are first hydrogenated to hydrogen sulfide in the Beavon Stretford Reactor (BSR), then they proceed to another Selectox reactor stage. Sulfur recoveries up to 99.3% w/w have been reported for BSR/Selectox.

Selexol Process

The Selexol process (unlike amine-based acid gas removal solvents that rely on a chemical reaction with the acid gases) uses a physical solvent made of dimethyl ethers of polyethylene glycol (DEPG, the Selexol solvent), to selectively remove hydrogen sulfide (H_2S) and carbonyl sulfide (COS) plus carbon dioxide (CO_2) in bulk from gas streams. The process is also effective for the removal of (and control of) mercaptan sulfur (RSH).

The process solvent (which is a widely used physical solvent process for gas cleaning) is a mixture of dimethyl ethers of polyethylene glycol $[\text{CH}_3(\text{CH}_2\text{CH}_2\text{O})_n\text{CH}_3]$ where n is between 3 and 9. The solvent is chemically and thermally stable, and has a low vapor pressure that limits its losses to the treated gas. The solvent has a high solubility for carbon dioxide, hydrogen sulfide, and carbonyl sulfide. It also has appreciable selectivity for hydrogen sulfide over carbon dioxide.

As with all physical solvent processes, the principal benefits are (i) high selectivity for hydrogen sulfide over carbonyl sulfide and carbon dioxide, (ii) high loadings at high acid gas partial pressures, (iii) solvent stability, and (iv) low heat requirements because most of the solvent can be regenerated by pressure letdown.

The Selexol process can be configured in various ways, depending on the requirements for the level of hydrogen sulfide/carbon dioxide selectivity, the depth of sulfur removal, the need for bulk carbon dioxide removal, and whether the gas needs to be dehydrated. The gas stream from the low-pressure flash is combined with the acid gas from the regenerator. This combined gas stream is then sent to a sulfur recovery unit. However, the hydrogen sulfide content could be too low for use in a conventional Claus plant. The process can also be configured to give both a rich acid gas feed to the Claus unit as well as to provide for bulk carbon dioxide removal.

Separation Processes – Definition and Characteristics

A separation process is any process that is designed to separate the products from the feedstock or to separate different products from each other or any combination of these two options.

A large number of different separation processes exist which are based on different techniques to generate a composition difference between the products of a process and the different processes into types defined by (i) the nature of the feedstock, (ii) the method of generating concentration differences, and (iii) whether or not the separation depended on the addition of special separating agents as well as energy.

Heterogeneous feedstocks contain more than one phase of matter (i.e., gas, liquid, or solid) and can contain almost any combination of gas liquid, liquid, or solid in a gas, liquid, or solid matrix. The exception is gas in gas systems, which are generally homogeneous except for some circumstances where a gas mixture very special mixtures which separate into two gaseous phases at high pressure. Many of the feedstocks encountered in alternative energy systems may be the heterogeneous type. Typical examples are slurries of solids, sludge, dusts, and mists in the products from manufacturing processes or incinerators; mixtures of solid phases encountered in ore processing or solid waste handling; and emulsions from metalworking plants. These types of feedstocks are separated by mechanical separation processes such as settling, centrifugation, flotation, filtration, magnetic separation, and electrostatic precipitation.

On the other hand, relatively simple mechanical equipment is needed to separate heterogeneous feedstocks into their individual phases; however, homogeneous feedstocks typically require a diffusional transfer of matter to one of the product streams. These processes generate two phases of different composition from the feedstock and then separate the phases to give two products of composition different from both the feedstock and each other. In some cases, the product phases may be in equilibrium when they are generated, as in simple distillation. Alternatively, the phases may be thoroughly mixed with one another to achieve equilibrium prior to phase separation. Examples of such equilibrium processes are distillation, extraction, adsorption, ion exchange, crystallization, and evaporation.

Unlike the equilibrium processes, some separation processes get the impetus from a gradient of temperature, pressure, and composition and achieve a change in composition of the product from differences in diffusion rate of

feed components through a barrier across which the gradient is applied. Processes of this type (typically referred to as rate-controlled processes) are illustrated by (i) membrane processes such as gaseous diffusion, ultrafiltration, reverse osmosis, and permeation, and (ii) processes depending on slow chemical reactions to make the separation, as in some carbon dioxide scrubbing processes that are designed to remove, say, carbon dioxide from a gas stream.

See also: Recovery Processes.

Separation Processes – Separation of Solids

The processes for separating various types of solid materials from each other are much different from the equilibrium processes used to separate liquids and gases. The processes for solids make use of physical differences in either a bulk property of the solids or in a surface property of the solids. Thus, the processes are more dependent on physical characteristics rather than on chemical characteristics and are essentially sorting processes.

A sorting process is a process that involves placing the components of a mixture into a specific place which involves separation of the mixture (of solid materials) into homogeneous groups according to the characteristics of the individual components. Typical examples of sorting processes in waste management are (i) the separation of glass, plastic, paper, and metals from each other, (ii) the separation of glass bottles into brown, green, and clear glass categories, (iii) the separation of plastic containers according to the type of polymer used in their manufacture, and (iv) separation of scrap metals or metal cans into ferrous and non-ferrous categories. These types of sorting processes are essential to permit effective recycling programs to be achieved, and the products of the process must not be cross-contaminated and must be homogeneous enough to be used as raw material in a manufacturing process.

For example, a sorting process (or sorting program) may involve the following steps: (i) the recyclable waste is placed on a presorting floor where paper materials – such as newspapers – and non-recyclable materials are removed. The remaining material is then put on conveyer belts and fed consecutively through separation devices which remove different materials and put them in separate bins for recycling.

For example, magnetic separation removes tramp iron and steel cans, while screening to remove fines eliminates sand and broken glass. Either air blowing or the chain curtain sorting machine is used to separate light aluminum and plastic containers from glass bottles and jars, after which the glass is then sorted by color either automatically or by hand. The large plastic bottles are removed by coarse screening, and the aluminum cans are removed by an eddy current magnetic separator. Finally, the plastic is separated by polymer type either manually or automatically.

The bulk properties typically chosen as a basis for sorting solids are size, density, magnetic permeability, or electrical conductivity. Solids are sorted by size over a wide size range using screens and rotating perforated drums. A combination of size and density controls the separation of solids in jigs and tables for larger sizes and in fluid beds or by elutriation for smaller sizes. The separation of solids according to density alone is usually achieved using a cyclone separator for small sizes and in cones and rotating drums for larger sizes.

A difference in the magnetic permeability between different solids is the basis for magnetic separation of many metals and mineral ores. It is also the basis for the separation of steel cans and steel scrap from trash. Finally, differences in the electrical conductivity of different solids make it possible to separate them using electrostatic forces. For example, insulating materials are slow to accept electrical charge but hold it well once charged. On the other hand, electrical conductors charge rapidly but also lose their charge rapidly. The surface properties of solids most frequently used as a basis for a separation process are surface tension, wettability, color, surface conductivity, and reflectance. Surface tension and wettability are the basis for separation of fine solids by flotation.

Processes for separation of solids by type of material can be divided into two major classes: (i) use of the properties of the solid to provide the force to do the separation, which includes magnetic separation processes, electrostatic separation, screening processes, and flotation processes, and (ii) automatic sorting which depends on monitoring a flowing stream of solids with a suitable detector which can distinguish between the types of solids to be separated – when the detector senses a material which is not of the desired type, it activates a mechanical device which removes that material from the flowing stream.

Settling and Flotation

Gravity settling is a commonly used process for separating insoluble particles of solids or liquids from a liquid or gaseous carrier fluid and the process involves the use of the effect of gravity on the difference in density between the dispersed particles and the carrier fluid in which the particles are dispersed. If the particles are more dense (heavier) than the carrier fluid, they sink to the bottom of the settling chamber. If the particles are less dense (lighter) than the carrier fluid, they rise to the surface of the liquid.

Gravity settling is a subcategory of the more general field of sedimentation, which includes the slower processes of hindered settling, flocculation, coagulation, clarification, and thickening.

Furthermore, gravity separation can be enhanced by the use of centrifuges and cyclones.

Flotation is also a gravity separation to remove insoluble particles from a liquid. However, it uses bubbles of gas, usually air, that attach to the insoluble particles and lift them to the surface of the liquid by buoyancy. The particles can then be removed from the surface by various skimming devices. By selectively attaching the bubbles to one particular kind of particle in a mixture, separation can be made between particles lifted to the surface and particles settled to the bottom.

Shell Gasification Process

The Shell gasification (partial oxidation) process is a flexible process for generating synthesis gas, principally hydrogen and carbon monoxide, for the ultimate production of high-purity high pressure hydrogen, ammonia, methanol, fuel gas, town gas or reducing gas by reaction of gaseous or liquid hydrocarbon derivatives with oxygen, air, or oxygen-enriched air. The most important step in converting the feedstock to industrial gas is the partial oxidation of the oil using oxygen with the addition of steam. The gasification process takes place in an empty, refractory-lined reactor at temperatures on the order of 1,400°C (2,550°F) and pressures between 29 to 1140 psi.

The chemical reactions in the gasification reactor proceed without catalyst to produce gas containing carbon amounting to some 0.5 to 2% by weight, based on the feedstock. The carbon is removed from the gas with water, extracted in most cases with feed oil from the water and returned to the feed oil. The high reformed gas temperature is utilized in a waste heat boiler for generating steam. The steam is generated at 850 to 1,565 psi. Some of the steam is used as process steam and for oxygen and oil preheating. The surplus steam is used for energy production and heating purposes.

See also: Gasification, Gasifiers.

Shell Gasifier

The Shell gasifier uses a pressurized, slagging entrained flow reactor for gasifying dry pulverized coal and has the potential to gasify a wide range of feedstocks. Unlike other gasifying systems, it uses pure oxygen as the gasifying medium.

In the process, the feedstock coal, before feeding to the gasifier vessel, is crushed and ground to a size less than 90 mm after which it is fed through diametrically opposite diffuser guns into the reaction chamber. The feedstock is then reacted with the pure oxygen and steam where the flame temperature reaches as high as 1,800 to 2,000°C at approximately 450 psi.

The raw product gas typically consists mainly of carbon monoxide and hydrogen with some quantities of carbon dioxide and nitrogen. A water-filled bottom compartment is provided where molten ash is collected. A quench section is provided at the reactor outlet. Removal of particulate matter from the raw gas is integrated with the overall process. This removal system consists of cyclones and scrubbers.

See also: Gasification, Gasifiers.

Shell-Paques Process

The Shell-Paques process for biological gas desulfurization integrates gas purification with sulphur recovery in one process unit. Hydrogen sulfide removal efficiencies greater than 99.8% can be reliably achieved, and treated gas can contain less than 4 ppm of hydrogen sulfide. The process is ideally suited to environmentally sensitive locations where flaring, incineration, or other combustion options are undesirable. Its application range is from 0.1 to 50 t/d of sulfur per unit.

In the process, a gas stream containing hydrogen sulfide contacts an aqueous soda solution containing sulfur bacteria in an absorber. The soda absorbs the hydrogen sulfide and is then transferred to a regenerator consisting of an aerated atmospheric tank where hydrogen sulfide is biologically converted to elemental sulfur. Sulfur may be recovered as a moist filter cake or as pure liquid sulfur.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Shell-Paques/Thiopaq Process

The Shell-Paques/THIOPAQ is a biological process for removing hydrogen sulfide from (high-pressure) natural gas, synthesis gas and refinery gas streams.

In this process, essentially complete removal of hydrogen sulfide can be achieved by selective biological conversion of hydrogen sulfide into elemental sulfur.

In comparison with conventional liquid redox processes significant savings in capital and especially operating costs can be achieved. In addition, economic savings can be delivered compared to conventional amine + Claus + SCOT technology for loadings of up to 50 ton sulfur/day; this upper limit increases continuously due to optimization of the process.

The sulfur produced has a hydrophilic nature, which significantly reduces the chance of equipment fouling or blocking. Moreover, this characteristic makes the product suitable for agricultural use as fertilizer. Alternatively, the sulfur can be melted to yield a high purity product which meets international Claus sulfur specifications.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Shell SGP Process

The Shell gasification process consists of three principal stages: (i) gasification, sometimes referred to as partial oxidation, in which the feedstock is converted to synthesis gas (syngas) in the presence of oxygen and a moderating agent (steam) in a refractory-lined gasification reactor, (ii) synthesis gas effluent cooler in which high pressure steam is generated from the hot synthesis gas leaving the reactor, and (iii) carbon removal, in which residual carbon and ash are removed from the synthesis gas in a two-stage water scrubbing unit. The final stage involves a soot water processing section, naphtha soot recycling unit (NSRU), or soot ash removal unit (SARU), which recovers carbon from the wash water and separates the metal ash from the carbon to yield a valuable product.

Both the feedstock and the gasification agent, oxygen, are preheated prior to being fed to the burner which is a proprietary co-annular burner specially designed for viscous feedstocks.

The partial oxidation reaction takes place at approximately 1,300 to 1,400°C (2,370 to 2,550°F) in the refractory-lined reactor. The sensible heat of the hot gas is used to generate high-pressure steam, with or without superheat as required. The non-catalytic partial oxidation reactor produces small amounts of soot that are washed out in a scrubber. The carbon is concentrated in the reaction water that is discharged to the wastewater treatment.

See also: Fischer Tropsch, Gasification, Synthesis Gas.

Shell SMDS Process

The Shell middle distillate synthesis (SMDS) process is a three-stage process that involves the Fischer-Tropsch synthesis of paraffinic wax called the high-boiling paraffin synthesis.

In the first stage synthesis, gas is obtained by partial oxidation of natural gas with pure oxygen in the Shell gasification process. In the second stage, high-boiling (high-molecular-weight) paraffin synthesis, the synthesis gas is converted into liquid hydrocarbon derivatives. In the third and final stage, the waxy syncrude is fractionated into high-quality products, a part of which is converted into middle distillates by means of the high-boiling paraffin (high-molecular-weight paraffin) conversion.

The heart of the process is an enhanced Fischer-Tropsch process. However, direct Fischer-Tropsch synthesis does not allow the selective production of materials of narrow carbon number range. To overcome this limitation, the flexible two-stage concept of SMDS combines the chain-length-independent Fischer-Tropsch chain-growth reaction with a chain-length-dependent cracking process. Naphtha, kerosene, and gas oil yield ratios can be varied from 15:25:60 to 25:50:25. Both the kerosene and gas oil show excellent combustion properties: the smoke point of the kerosene can be over 45 mm, and the gas oil has a cetane number in excess of 70.

The wax (high-molecular-weight paraffin) is subsequently hydrocracked and isomerized (in the presence of hydrogen) to yield a middle distillate boiling range product in the high-boiling paraffin conversion. In the high-boiling paraffin synthesis stage, wax is maximized by using a proprietary catalyst having high selectivity toward higher-boiling products and by the use of a tubular, fixed-bed reactor. The high-boiling paraffin conversion high-boiling paraffin conversion stage employs a commercial hydrocracking catalyst in a trickle flow reactor. The high-boiling paraffin conversion step allows for production of narrow range hydrocarbon derivatives not possible with conventional Fischer-Tropsch technology.

The products manufactured are predominantly paraffinic, free from sulfur, nitrogen, and other impurities, and have excellent combustion properties. The high cetane number and smoke point indicate clean-burning hydrocarbon liquids having reduced harmful exhaust emissions. The process can also be proposed to produce chemical intermediates, paraffinic solvents, and extra high viscosity index lube oils.

Shift Conversion

The second important reaction in a steam reforming plant is the shift conversion reaction:

Two basic types of shift catalyst are used in steam reforming plants: iron/chrome high temperature shift catalysts, and copper/zinc low temperature shift catalysts.

High-temperature shift catalysts operate in the range of 315 to 430°C (600 to 800°F) and consist primarily of magnetite (Fe_3O_4) with trivalent chromium oxide (Cr_2O_3) added as a stabilizer. The catalyst is usually supplied in the form of ferric oxide (Fe_2O_3) and six-valent chromium oxide (CrO_3) and is reduced by the hydrogen and carbon monoxide in the shift feed gas as part of the start-up procedure to produce the catalyst in the desired form. However, caution is necessary since if the steam/carbon ratio of the feedstock is too low and the reducing environment too strong; the catalyst can be reduced further, to metallic iron. Metallic iron is a catalyst for Fischer-Tropsch reactions, and hydrocarbon derivatives will be produced.

Low-temperature shift catalysts operate at temperatures on the order of 205 to 230°C (400 to 450°F). Because of the lower temperature, the reaction equilibrium is more controllable and lower amounts of carbon monoxide are produced. The low-temperature shift catalyst is primarily used in wet scrubbing plants that use methanation for final purification. Pressure swing adsorption plants do not generally use a low-temperature because since any unconverted carbon monoxide is recovered as reformer fuel. Low-temperature shift catalysts are sensitive to poisoning by sulfur and are sensitive to water (liquid) that can cause softening of the catalyst followed by crusting or plugging.

The catalyst is supplied as copper oxide (CuO) on a zinc oxide (ZnO) carrier, and the copper must be reduced by heating it in a stream of inert gas with measured quantities of hydrogen. The reduction of the copper oxide is strongly exothermic and must be closely monitored.

Short Rotation Coppice

Short rotation coppice (SRC, or short rotation woody crops) refers to fast-growing deciduous trees which are grown as energy crops, such as willow and poplar trees. The species of short rotation coppice that are most suitable, and therefore most popular, for use as energy crops are poplar and willow (and possibly also birch) because they both require deep, moisture-retentive soils for proper growth. Willow, in particular, is able to endure periods of water logging and is therefore better suited to wetter soil.

Short rotation coppice is harvested on a 2-to-5-year cycle, although commonly every 3 years. Willow and poplar are adapted to cool climates and tolerate temporary wet conditions better than most of other species.

The harvesting of the wood takes place at the vegetative rest during the winter months. At this time of the year, the wood has a water content of around 50 %. Harvesting can be carried out using three main methods which are (i) the coppice is cut and bundled in bundles, (ii) the coppice is cut and chipped in a single operation, then blown into a trailer, and (iii) an intermediate system where the coppice is cut into billets and blown into a trailer. After harvesting, the product may be stored for a few weeks in order to reduce its moisture content to a satisfactory level for use in energy production. Dry short rotation coppice can then be burnt under controlled conditions to produce other fuels, gas or liquid, which are then used for electricity generation.

A plantation could be viable for up to 30 years before re-planting becomes necessary, although the yield decreases after 5-6 rotations.

Short rotation coppice (SRC) (such as willow and poplar) is densely planted, high-yielding varieties. It is harvested on a 2-to-5-year cycle, although commonly every 3 years. Willow and poplar are adapted to cool climates and tolerate temporary wet conditions better than most of other species. The harvesting of the wood takes place at the vegetative rest (November to February). At this time of the year, the wood has a water content of around 50%. Performance of short rotation coppice depends on the selection of species, environmental conditions, fertilizers, soil, etc. and can reach up to 20 t/ha. However, usually, yield ranges from 5 to 15 t/ha of dry matter. Harvesting can

be carried out using 3 main methods: the coppice is cut and bundled in bundles; the coppice is cut and chipped in a single operation, then blown into a trailer; and an intermediate system where the coppice is cut into billets and blown into a trailer. Performance of short rotation coppice can be harvested with chopper machinery, called a chopper harvester. But conventional machineries are not really adapted for harvesting.

The species of short rotation coppice that are most suitable, and therefore most popular, for use as energy crops are poplar and willow (and possibly also birch) because they both require deep, moisture-retentive soils for proper growth. Willow, in particular, is able to endure periods of water logging and is therefore better suited to wetter soils. Short rotation coppice is harvested during winter when the dry matter percentage of the coppice is at its highest, and it is then bundled or immediately chipped. It may then be stored for a few weeks in order to reduce its moisture content to a satisfactory level for use in energy production. Dry short rotation coppice can then be burnt under controlled conditions to produce other fuels, gas or liquid, which are then used for electricity generation.

See also: Short Rotational Coppicing, Biomass, Wood.

Short Rotational Coppicing

Short rotational arable coppicing is currently viewed by some as a potentially important source of fuel for electricity generation.

Crops tend to be established by planting cuttings in cultivated ground. Coppicing occurs every 2 to 4 years when stems are harvested by cutting 3 to 4 inches above ground level (cutting cycle). Cutting cycles can vary depending on the objectives of management and available land.

Energy crops include (i) willows, (ii) poplars, (iii) hemp, (iv) miscanthus, which is a temperate climate grass adapted to moist soils and sewage sludge can be used as fertilizer for this plant, (v) maize, and (vi) sorghum, which is a grass-like grain crop that produces sugars.

Willow has been the main tree species highlighted for short rotational coppicing – poplar may also be used and produces large amounts of biomass in relatively short periods due to its fast-growing nature. In addition, willow will thrive in a wide range of soil types and can be grown from cuttings, provided there is an adequate water supply (and as far as “sunny” Scotland is concerned, this does not pose a problem). Care needs to be taken to control weeds and protect new plantations from rabbits and deer. During growth, the use of fertilizers and chemicals is lower than for most agricultural crops. The willow can be cut back at the end of the first year as this encourages growth of multiple shoots; alternatively, plantations could be removed and the land returned to agricultural crops if things are not going as planned. Yields from coppicing can be stored until needed and then used to generate heat and electricity.

See also: Short Rotational Coppice; Wood.

Short Rotation Forestry

The dedicated cultivation of short-rotation (over a total period of 3 to 30 years) wood species is recently getting an increasing popularity in Europe. Willow (*Salix*) and to a lesser extent – poplar (*Populus*) are the favorite species.

Willow is harvested in 2-to-4-year intervals, when the shoots are approximately of 20 feet of height, normally in the winter in order to reduce the moisture content. After harvesting, willow stumps are left to coppice and another crop grows in 2 to 4 years. Poplar needs longer harvest intervals – 8 to 15 years.

Achieving high yields is only possible under specific cultivation conditions. For instance, poplar and especially willow require substantial quantities of water, i.e., the growth rate is reduced in dry conditions or dry years. The cultivation of short rotation forestry could also result in groundwater depletion. Nevertheless, planting perennial short rotation forestry brings some clear environmental benefits, compared to growing conventional annual crops – less soil disturbance and more soil cover (leading to reduced soil erosion), lower fertilizer, and pesticide inputs.

The cultivation and harvesting of short rotation forestry is also very energy-efficient since it consumes little energy – only 4 to 5% of the energy content of the harvested material. The core drawback of dedicated woody crops is the much higher cost compared to various wood residues from thinning as well as the pulp and paper industry.

Hence, the reduction of cultivation costs of short rotation forestry is a main challenge and prerequisite for its larger utilization.

Another drawback of woody crops is the typically high moisture content that is not appropriate for the gasification process. Thus, the woody feedstock from short rotation forestry typically requires pre-drying.

Sinapyl Alcohol

Sinapyl alcohol is an organic compound structurally related to cinnamic acid. It is biosynthesized via the phenylpropanoid biochemical pathway, its immediate precursor being sinapaldehyde. This phytochemical is one of the monolignols, which are precursor to lignin or lignans.

Sinapyl alcohol

Sinapyl alcohol is slightly soluble (in water) and is a very weakly acidic compound.

See also: Coniferyl Alcohol, Lignin, Paracoumaryl Alcohol.

Sizing

Sizing of the feedstock may be necessary as different sizes are specified for different types of gasifiers. For small-scale fixed bed gasifiers, cutting and/or sawing of wood blocks is the preferred form of fuel preparation. Chipped wood is preferred for larger scale applications. The size range of chips can be chosen by screening such that the fuel is acceptable for a specific gasifier type. For medium- and large-scale fixed bed gasifiers, wood chips from forestry or wood processing industries are produced by crushers, hammer mills, shredders, and/or mobile chippers (particularly for thinnings from landscape conservation activities). Most of these sizing apparatus are provided with a screen. Dependent on the feedstock morphology and characteristics (hardness), the throughput or capacity varies considerably.

See also: Gasification.

Slagging, Fouling, and Clinkering

Slagging is the accumulation of ash on the wall tubes of a boiler furnace, forming a solid layer of ash residue and interfering with heat transfer. It is the fused or resolidified molten materials that form primarily on furnace walls or other surfaces. Slag usually forms at locations where temperatures are high. Changes to slagging potential affect furnace sizing, arrangement of radiant and convective heating surfaces, and the number of soot blowers required.

During combustion, there are zones in which the supply of oxygen is depleted or carbon dioxide is reversibly reduced to carbon monoxide in the presence of excess carbon. This can produce a reducing atmosphere in a hot zone where ash particles in an incipient state of fusion begin to melt. The significance of performing the test in reducing and oxidizing atmospheres is that most oxides of metals exhibit higher fusion temperatures in their highest state of oxidation.

The critical temperature most commonly referenced in the evaluation of the properties of ash is the softening temperature. This is the temperature at which the cone has fused down to a spherical lump in which the height is equal to the width at the base.

Slagging Lurgi Gasifier

The major disadvantage of the dry ash Lurgi gasifier is that temperatures have to be maintained below the ash melting point to prevent clinking. As a consequence, steam utilization is poor and efficiencies are relatively low. Moreover, low reactivity coals are of concern since they require higher steam/oxygen ratios to hold down the temperature. To improve the performance of the gasifier—and in line with the current leaning toward high temperature operation for increased reaction rates, higher steam utilization, and reduced methane formation—a slagging version of the gasifier has been developed. This work was initiated in Germany in the 1954 to 55 time period, and since then was continued sporadically in Britain.

The top of the slagging gasifier is identical to the dry ash unit, while the bottom part has been modified. The ash melts at the high temperatures reached in the combustion zone, up to 2,000°C (3,630°F), and forms a slag which runs into the quench chamber – a water bath in which the slag forms small granules of solid ash. Temperatures, and therefore reaction rates, are high in the gasification zone so that the coal residence time is approximately 20 minutes, or one-third of that in the dry ash Lurgi. Steam decomposition approaches 100%, and because the off gas now has less heat capacity, top temperatures are very much dependent on the moisture content of the coal, as is the steam content of the off gas.

In addition to improved steam decomposition, the higher temperatures also result in lower carbon dioxide concentrations due to the formation of carbon monoxide via the Boudouard reaction. The hydrogen-to-carbon monoxide ratio in the off gas is typically 0.5 in comparison with 2 for the dry ash Lurgi. The off gas still contains methane, but this is probably derived from devolatilization at the top of the gasifier rather than by carbon hydrogenation. The off gases in fact contain more tars and oils than in the dry ash system, apparently because of the lower heat capacity of the off gases and consequently lower top temperatures.

See also: Gasification, Gasifiers.

Sludge

Sludge is a type of chemical waste is waste is a general term and covers many types of materials but is generally recognized as a waste that is composed of harmful chemicals. Thus, by this definition, organic chemical waste is composed of harmful chemicals. On the other hand, activated sludge consists of sludge particles containing living organisms, produced in either raw or settled wastewater by the growth of organisms (which include bacteria) in aeration tanks where dissolved oxygen is present.

The wastewater treatment industry describes sludge as a waste stream resulting from wastewater treatment. This description does not provide a physical or chemical basis for a definition but is adequate for the needs of wastewater treatment plant (WWTP) operations (i.e., anyone can distinguish between the treated effluent, which flows out of the plant, and the material that is pumped, scraped, or skimmed from the treatment units).

One option is to define sludge on the basis of the solids content (Figure S-1), but in order to develop a quantitative definition of sludge which will also help with correlating waste forms with disposal options, a simple and measurable characteristic of all three waste forms needs to be identified.

<i>Waste form</i>	<i>Solid,</i>	<i>Sludge</i>	<i>Liquid</i>
<i>Total solids, % w/w</i>	50 to 100	1 to 50	<1%

Figure S-1 Simplified distinction between solid waste, sludge, and liquid waste.

Slurry Phase Reactor

The latest development of Fischer-Tropsch technology is the Sasol slurry phase reactor, which might also be applicable to the production of fuels from biomass. This reactor is an integral part of the Sasol slurry phase distillate

(SSPD) process, and carries out the synthesis gas reaction at low temperatures (200 to 250°C; 390 to 480°F) and low pressures.

The process involves bubbling hot synthesis gas through a liquid slurry of catalyst particles and liquid reaction products. Heat is removed from the reactor via coils within the bed producing steam. Liquid products are removed from the reactor, and the liquid hydrocarbon wax separated from the catalyst. The gas stream from the top of the reactor is cooled to recover low-boiling hydrocarbon derivatives and reaction water. The Sasol slurry phase technology has undergone several developments primarily concerned with catalyst formulations. Initial development used an iron-based catalyst, but recent developments have used a cobalt-based catalyst, giving greater conversion.

See also: Synthesis Gas.

Smog

Smog (a term that is a combination of the words smoke and fog) is made up of suspended particulates, which are formed by a complex reaction between various oxides of nitrogen and a wide range of hydrocarbon derivatives, which is triggered by sunlight. Smog is a combination of various gases with water vapor and dust. A large part of the gases that form smog is produced when fuels are burnt. Smog forms when heat and sunlight react with these gases and fine particles in the air. Smog can affect outlying suburbs and rural areas as well as big cities. Its occurrences are often linked to heavy traffic, high temperatures, and calm winds. Heavy smog greatly decreases ultraviolet radiation. Smog and acid rain might be considered to be the end-point of emissions from the use of natural gas.

Particulate emissions also cause the degradation of air quality in the United States. These particulates can include soot, ash, metals, and other airborne particles. In fact, sulfur and nitrate effluents form small particles $PM_{2.5}$ (particulate matter that is on the order of 2.5 microns in diameter) that can (and will) irritate eyes and nasal cavity, also particulate matter ($PM_{2.5}$) can enter the blood stream of humans (and animals) and adversely affect the heart and lungs.

Global warming or the greenhouse effect is an environmental issue that deals with the potential for global climate change due to increased levels of atmospheric greenhouse gases. There are certain gases in the atmosphere that serve to regulate the amount of heat that is kept close to the surface of the Earth. Scientists theorize that an increase in these greenhouse gases will translate into increased temperatures around the globe, which would result in many disastrous environmental effects.

The principle greenhouse gases include water vapor, carbon dioxide, methane, nitrogen oxides, and some engineered chemicals such as chlorofluorocarbons. While most of these gases occur in the atmosphere naturally, levels have been increasing due to the widespread burning of fossil fuels by growing human populations. The reduction of greenhouse gas emissions has become a primary focus of environmental programs in countries around the world.

One of the principle greenhouse gases is carbon dioxide. Although carbon dioxide does not trap heat as effectively as other greenhouse gases (making it a less potent greenhouse gas), the sheer volume of carbon dioxide emissions into the atmosphere is high, particularly from the burning of fossil fuels.

Because carbon dioxide makes up such a high proportion of U.S. greenhouse gas emissions, reducing carbon dioxide emissions can play a huge role in combating the greenhouse effect and global warming. The combustion of natural gas emits almost 30% less carbon dioxide than oil, and just under 45% less carbon dioxide than coal.

One issue that has arisen with respect to natural gas and the greenhouse effect is the fact that methane, the principle component of natural gas, is itself a very potent greenhouse gas. In fact, methane has an ability to trap heat almost 21 times more effectively than carbon dioxide.

Methane emissions account for only 1.1% of total U.S. greenhouse gas emissions, they account for 8.5% of the greenhouse gas emissions based on global warming potential. Sources of methane emissions in the U.S. include the waste management and operations industry, the agricultural industry, as well as leaks and emissions from the oil and gas industry itself. A major study performed by the Environmental Protection Agency (EPA) and the Gas Research Institute (GRI) in 1997 sought to discover whether the reduction in carbon dioxide emissions from increased natural gas use would be offset by a possible increased level of methane emissions. The study concluded that the reduction in emissions from increased natural gas use strongly outweighs the detrimental effects of increased methane emissions. Thus, the increased use of natural gas in the place of other, dirtier fossil fuels can serve to lessen the emission of greenhouse gases in the United States.

Smog and poor air quality are a pressing environmental problem, particularly for large metropolitan cities. Smog, the primary constituent of which is ground level ozone, is formed by a chemical reaction of carbon monoxide, nitrogen oxides, volatile organic compounds, and heat from sunlight. As well as creating that familiar smoggy haze commonly found surrounding large cities, particularly in the summer time, smog, and ground-level ozone can contribute to respiratory problems ranging from temporary discomfort to long-lasting, permanent lung damage. Pollutants contributing to smog come from a variety of sources, including vehicle emissions, smokestack emissions, paints, and solvents. Because the reaction to create smog requires heat, smog problems are the worst in the summertime.

The use of natural gas does not contribute significantly to smog formation, as it emits low levels of nitrogen oxides, and virtually no particulate matter. For this reason, it can be used to help combat smog formation in those areas where ground-level air quality is poor. The main sources of nitrogen oxides are electric utilities, motor vehicles, and industrial plants. Increased natural gas use in the electric generation sector, a shift to cleaner natural gas vehicles, or increased industrial natural gas use could all serve to combat smog production, especially in urban centers where it is needed the most. Particularly in the summertime, when natural gas demand is lowest and smog problems are the greatest, industrial plants and electric generators could use natural gas to fuel their operations instead of other, more polluting fossil fuels. This would effectively reduce the emissions of smog causing chemicals, and result in clearer, healthier air around urban centers. For instance, a 1995 study by the Coalition for Gas-Based Environmental Solutions found that in the Northeast, smog and ozone-causing emissions could be reduced by 50 to 70% through the seasonal switching to natural gas by electric generators and industrial installations.

Particulate emissions also cause the degradation of air quality in the United States. These particulates can include soot, ash, metals, and other airborne particles. Natural gas emits virtually no particulates into the atmosphere: in fact, emissions of particulates from natural gas combustion are 90% lower than from the combustion of oil, and 99% lower than burning coal.

Acid rain is another environmental problem that affects much of the Eastern United States, damaging crops, forests, wildlife populations, and causing respiratory and other illnesses in humans. Acid rain is formed when sulfur dioxide and nitrogen oxides react with water vapor and other chemicals in the presence of sunlight to form various acidic compounds in the air. The principle source of acid rain-causing pollutants, sulfur dioxide and nitrogen oxides, are coal-fired power plants. Since natural gas emits virtually no sulfur dioxide, and up to 80% less nitrogen oxides than the combustion of coal, increased use of natural gas could provide for fewer acid rain-causing emissions.

See also: Acid Rain, Greenhouse Effect.

Smog Formation

Smog is a pressing environmental problem, particularly for large metropolitan cities. The primary constituent of smog is ground-level ozone created by photochemical reactions in the near-surface atmosphere involving a combination of pollutants from many sources, including motor vehicle exhausts, volatile organic compounds such as paints and solvents, and smokestack emissions. Because the reaction to create smog requires heat, smog problems are the worst in the summertime.

Natural gas use is not much of a factor in smog formation. As opposed to crude oil products and coal, the combustion of natural gas results in relatively small production of smog-forming pollutants as it emits low levels of nitrogen oxides, and virtually no particulate matter. For this reason, it can be used to help combat smog formation in those areas where ground-level air quality is poor. The smog-forming pollutants literally cook in the air as they mix together and are acted on by heat and sunlight. The wind can blow smog-forming pollutants away from their sources while the reaction takes place, explaining why smog can be more severe miles away from the source of pollutants than at the source itself.

Sodasol Process

During washing with lye solution (alkaline solution), the lye removes only the lighter or lower-boiling mercaptans, but various chemicals can be added to the lye solution to increase its ability to dissolve the higher-boiling mercaptan

derivatives. The added chemicals are generally known as solubility promoters or solutizers that differ chiefly in the composition of the solutizers.

In the process, the treating solution is composed of lye solution and alkyl phenols (acid oils), which occur in cracked naphtha and cracked gas oil and are obtained by washing cracked naphtha or cracked gas oil with the lye solution. The lye solution, with solutizers incorporated, is then ready to treat product streams, such as straight-run naphtha and kerosene. The process is carried out by pumping a sour stream up a treating tower countercurrent to a stream of Sodalol solution that flows down the tower. As the two streams mix and pass, the solution removes mercaptans and other impurities, such as oxygen compounds (phenols and acids), as well as some nitrogen compounds.

The treated stream leaves the top of the tower; the spent Sodalol solution leaves the bottom of the tower to be pumped to the top of a regeneration tower, where mercaptans are removed from the solution by steam. The regenerated Sodalol solution is then pumped to the top of the treatment tower to treat more material.

A variation of the Sodalol process is the Potasol process, which uses potassium hydroxide instead of lye (sodium hydroxide).

Sofnolime RG Process

The Sofnolime RG process is an *alkaline solids dry sorption process* that makes use of a hydroxide media similar to that of caustic scrubbing processes. It is a dry process that claims it has a synergistic mixture of hydroxides in a granular solid. The media is capable of removing H₂S, CO₂, COS, SO₂, and organic sulfur compounds. The process employs the following reactions:

Sofnolime RG removes both H₂S and CO₂. Gas streams with high carbon dioxide content will exhaust the media rapidly. The packed bed is supported between layers of ceramic balls on the top and bottom, with the flow direction in the upward direction.

Softwood

In the current context of using wood as an alternate energy source, a description of the different types of pore system is worthy of note since the type of wood and the distribution patterns of the pore systems can have a strong influence the processibility of the wood.

As with hardwood, becoming familiar with wood characteristics and structure, as well as the techniques used to identify them, requires practice and dedication. If you know what to look for and where to look to identify any unique characteristics, thereby enabling accurate and efficient wood identification.

The first step after making the determination that a wood specimen is softwood – due to the absence of pores – is to inspect the cross-section surface for the presence of resin canals. Resin canals are tubular passages in wood that exude pitch, or resin, to seal off wounds that occur due to insect or mechanical damage. Resin canals most often occur in or near the latewood zone of the growth rings. Softwoods can be separated into two classifications based on the presence or absence of resin canals. Species that have resin canals include pine trees, spruce trees, larches, and Douglas fir trees. The species that do not have resin canals include firs, hemlocks, cedars, redwood, bald cypress, and yew.

Woods with resin canals are further separated into two groups: (i) those with large resin canals, such as pines, and (ii) those with small resin canals, such as Douglas fir, spruce, and larch. Using a sample wood identification set to compare the size and number of resin canals of different species is useful in determining how much they

can differ between species. For example, most pines have quite large and numerous resin canals that can be seen without the aid of a hand lens. Spruce and larch, on the other hand, have much smaller resin canals that occur less frequently. Douglas fir has many small resin canals. Because the presence of resin canals is quite variable, it may be necessary to make several cuts on the cross section of a specimen to uncover enough surface area to make a good determination.

As with the hardwoods, color, odor, and density are useful characteristics in identifying softwoods. Some species have distinct color differences, while others do not. Eastern white pine is consistently yellowish white, darkening to light brown with age. Eastern redcedar has a distinctive deep purplish-red color, and redwood a deep reddish-brown. Examples of odors include the pine-type fragrance of pines, the cedar-type scent of eastern red cedar, and the relative absence of smell in spruce trees and fir trees.

Softwoods also vary substantially in density. Because many species are quite dense and strong, softwood lumber is typically used for structural or construction purposes. Southern yellow pine, spruce, hemlock, fir, and Douglas fir are all commonly used in the construction industry. White pine and cedars, on the other hand, are considerably less dense and lighter in weight than the other species, while white pine and cedars are easier to slice with a razor blade when preparing a surface for identification.

See also: Hardwood, Wood, Wood – Hardwood, Wood – Softwood.

Softwood Residues

Softwood residues are generally in high demand as feedstocks for paper production, but hardwood timber residues have less demand and fewer competing uses. In the past, as much as 50% of the tree was left on site at the time of harvest. Whole tree harvest systems for pulp chips recover a much larger fraction of the wood. Wood harvests for timber production often generates residues which may be left on the site or recovered for pulp production. Economics of wood recovery depend greatly on accessibility and local demand. Underutilized wood species include Southern red oak, poplar, and various small diameter hardwood species.

Unharvested dead and diseased trees can comprise a major resource in some regions. When such timber has accumulated in abundance, it comprises a fire hazard and must be removed. Such low-grade wood generally has little value and is often removed by prescribed burns in order to reduce the risk of wildfires.

Soil

Soil is an important aspect of any environmental studies because, on the land, the soil is often the major recipient of any spilled chemical(s). Soil covers most of the land surfaces as a continuum, and each soil grades into the rock materials below and into other soils at its margins, where changes occur in relief, groundwater, vegetation, kinds of rock, or other factors which influence the development of soils. The organic and inorganic material in which soils form is the parent material. Soil can be conveniently subdivided into various soil types, each with different composition and properties (Table S-1, Table S-2).

Table S-1 Types of soils based on composition.

Classification	% w/w clay	% w/w silt	%w/w sand
Clay soil	40-100	0-40	0-45
Loam soil	7-27	28-50	23-52
Sandy soil	1-10	1-15	85-100%

Table S-2 Types of soils based on properties.

Soil type*	Descriptions
Alluvial soil	Formed as a result of deposition by the rivers and streams; lacks a well-developed profile; supports luxuriant growth of vegetation.
Chernozemic soil	Occurs in humid to semi-arid temperate climatic conditions under grasses.
Desertic soil	Found in arid climatic conditions.
Latosolic soil	Develops in humid tropical or semitropical-forested regions.
Mountain soil	Occurs in hilly regions under colder climates.
Podzolic soil	Also called podzolonc soil; found in humid temperate climate, under forest vegetation.
Saline soil	Occurs in the dry climates where rapid evaporation of water results in surface deposition.
Tundra soil	Develops in colder regions and under vegetation such as lichens, mosses, herbs, and shrubs.

*Listed alphabetically.

The formation of soil involves the formation of unconsolidated materials by the weathering which leads to the development of the soil profile. During weathering, the physical disintegration and chemical decomposition of the rocks and minerals contained in them occurs. The physical disintegration process is the breakdown of rock into smaller fragments and eventually into sand and silt particles that are commonly made up of individual minerals. Simultaneously, mineral decomposition occurs and soluble materials released and new minerals are often created. The new minerals form either by minor chemical alterations or by a complete chemical breakdown of the original mineral, thereby leading to the creation of new minerals. Based on the location of soil mineral particles formation and deposition, the soils are classified as *residual soil* and *transported soil*. Residual soil is the soil that has been formed in place from the bedrock below. On the other hand, transported soil is soil in which the mineral particles have been carried from some other location by wind, water, gravity, or ice. Furthermore, the transported soil can be classified (alphabetically) into (i) alluvium, which is soil that has been transported by the movement of water, (ii) colluvium, which is soil that has been transported by gravity, (iii) eolian soil, which is soil that has been transported by wind, and (iv) glacial soil, which is soil that has been transported by the movement of glaciers.

Mineral soils that are formed directly from the weathering of bedrock, the solid rock that lies beneath the soil; therefore, they have a similar composition to the original rock. Other soils form in materials that came from elsewhere, such as sand and glacial drift. Materials located in the depth of the soil are relatively unchanged compared with the deposited material. Sediments in rivers may have different characteristics, depending on whether the stream moves quickly or slowly. A fast-moving river could have sediments of rocks and sand, whereas a slow-moving river could have fine-textured material, such as clay.

Thus, soil is a mixture of organic matter, minerals, gases, and liquids, and organisms that together support life on the Earth. The soil on the earth (the pedosphere) has four important functions which are (i) a medium for plant growth, (ii) a medium for water storage, supply, and purification, (iii) a modifier of the atmosphere of the Earth, and (iv) a habitat for organisms. The soil is the most important part of any land system insofar as it is the medium upon which virtually all terrestrial organisms depend upon it for their existence. The productivity of soil is strongly affected by environmental conditions and pollutants.

Soil is a product of several factors, some of which are (i) the influence of climate, (ii) elevation, orientation, and slope of terrain, (iii) organisms, and (iv) the parent materials of the soil (i.e., the original minerals) interacting over time. Also, the soil continually undergoes development by way of numerous physical, chemical, and biological processes, which include weathering and the associated erosion.

Most soils have a dry bulk density (density of soil taking into account voids when dry) between 1.1 g/cm^3 and 1.6 g/cm^3 , while the soil particle density is much higher, typically in the range of 2.6 to 2.7 g/cm^3 . In engineering terms, soil is included in the broader concept of regolith, which also includes other loose material that lies above the bedrock, as can be found on the Moon and on other celestial objects as well.

Soil is the receptor of chemical waste from landfill leachate, lagoons, and other sources. Contamination of the soil refers to addition of soil constituents, due to domestic, industrial, and agricultural activities, that were originally absent in the system. Soil contamination is of two different kinds: (i) the slow but steady degradation of soil quality (such as organic matter, nutrients, water-holding, capacity, porosity, and purity) due to contaminants such as domestic and industrial wastes or chemical inputs from agriculture, and (ii) the concentrated pollution of smaller areas, mainly through dumping or leakage of wastes. The sources of contamination include the weathering of geological parent materials, where element concentrations exceed the natural abundances in wet or dry deposition forms. More specifically, a number of metals and chemicals are commonly regarded as contaminants of soil and include heavy metals as well as metalloids and nonmetals. The main elements implicated as contaminants are arsenic, cadmium, chromium, copper, fluorine, lead, mercury, nickel, and zinc. In addition, beryllium, bismuth, selenium, and vanadium may also be dangerous.

In some cases, land farming of degradable organic wastes is practiced as a means of disposal and degradation. The degradable material is worked into the soil, and soil microbial processes cause the degradation of the material, as for example by the application of sewage and fertilizer-rich sewage sludge to soil.

Soil is a finely divided rock-derived material containing organic matter and capable of supporting vegetation. Soils are independent natural bodies, each with a unique morphology resulting from a particular combination of climate, living plants and animals, parent rock materials, relief, the groundwater, and age.

Soil is a variable mixture of minerals, organic matter, as well as water and is the final product of the weathering action of physical, chemical, and biological processes on rocks. The organic portion of soil consists of plant biomass in various stages of decay. High populations of bacteria, fungi, and animals such as earthworms may be found in soil. The presence of living organisms greatly affects soil formation and structure. Animals and microorganisms can produce pores and crevices. Plant roots can penetrate into crevices to produce more fragmentation. Plant secretions promote the development of microorganisms around the root in an area known as the rhizosphere. Additionally, leaves and other material that fall from plants decompose and contribute to soil composition.

Approximately 35% v/v of a typical soil is composed of air-filled pores. As a point of reference, the atmosphere at sea level contains 21% v/v oxygen and <0.1% v/v carbon dioxide. These amounts may be quite different in soil air because of the decay of organic matter which produces carbon dioxide by consumption of oxygen. As a result, the oxygen content of air in soil may be as low as 15% v/v and the carbon dioxide content may be several percent.

The description of the soil profile commences at the underlying rock which supplies the parent material for the formation of soil; a series of layers are developed. Each layer is called a soil horizon and the sequence of horizons. There are five main types of horizons (layers) in soil which are denoted as O, A, B, C, and R horizons. Each horizon is different from the others in terms of the properties, such as color, texture, structure, consistency, porosity, and reactivity.

The O-horizon is the topmost portion of soil and consists of organic matter and is commonly found in forest soils. It is further subdivided into (i) the O1 horizon, which is the organic horizon wherein the original forms of plant and animals residues can be recognized by the naked eye, the O2 horizon in which the original plant and animal forms cannot be distinguished by the naked eye, (ii) the A-horizon is the mineral horizon, which lies at or near the surface and is recognized as the zone of maximum leaching or eluviation, and (iii) the B-horizon which is the layer below the A layers in which there is the accumulation of iron and aluminum oxide and silicate clay minerals the occurs and is sometimes also referred to as subsoil and is further divisible in B1, B2, and B3 horizons. The R Horizon represents the bedrock from which the other horizons may have originated (Sigel and Sigel, 1995).

Typically, the A, B, C, and R horizons are parallel (or near-parallel) to the surface of the Earth and may be thick or thin. The horizons may be prominent or so weak that they can be detected only in the laboratory. In general, the boundary of soils with the underlying rock or rock material occurs at depths ranging from 1 to 6 feet, though the extremes lie outside this range. Rainwater percolating through soil carries dissolved and colloidal solids to lower horizons where they are deposited.

One of the more important classes of productive soils is the podzol type of soil which are soils formed in temperate-to-cold climates under relatively high rainfall conditions under coniferous or mixed forest or heath vegetation. These generally rich soils tend to be acidic (pH 3.5-4.5) such that alkali and alkaline earth metals and, to a lesser extent aluminum and iron, are leached from the A horizon, leaving kaolinite as the predominant clay mineral. At somewhat higher pH in the B horizon, hydrated iron oxides and clays are redeposited.

The mechanical properties of soil are largely determined by particle size. The four major categories of soil particle sizes are (i) gravel, 2 to 60 mm, (ii) sand, 0.06 to 2 mm, (iii) silt, 0.06 to 0.006 mm, and (iv) clay minerals, <0.002 mm. Clays represent a size fraction rather than a specific class of mineral matter. Soil receives large quantities of contaminants as a result of a variety of activities. Pesticides are a particular contaminant because of their application to crops.

Cation exchange in soil is the mechanism by which potassium, calcium, magnesium, and essential trace-level metals are made available to plants. When nutrient metal ions are taken up by plant roots, a hydrogen ion is exchanged for the metal ions. This process, and the leaching of calcium, magnesium, and other metal ions from the soil by water containing carbonic acid, tends to make the soil acidic.

In addition to being the site of most food production, soil is the receptor of large quantities of pollutants, such as particulate matter from power plant smokestacks. Fertilizers and some other materials applied to soil often contribute to water and air pollution. Therefore, soil is a key component of environmental chemical cycles; soils are open systems that undergo continual exchange of matter and energy with the atmosphere, hydrosphere, and biosphere.

Solar Collectors

Typically, the term solar collector refers to a device that collects and/or concentrates solar radiation from the Sun. These devices are primarily used for active solar heating and allow for the heating of water for personal use. These collectors are generally mounted on the roof and must be very sturdy as they are exposed to a variety of different weather conditions. As well as in domestic settings, a large number of these collectors can be combined in an array and used to generate electricity in solar thermal power plants.

There are many different types of solar collectors (examples are presented below), but all are constructed with the same basic premise in mind. In general, there is some material that is used to collect and focus energy from the Sun and use it to heat water. The simplest of these devices uses a black material surrounding pipes that water flows through. The black material absorbs the solar radiation very well, and as the material heats up the water it surrounds. This is a simple design, but collectors can be complex. Absorber plates can be used if a high temperature increase isn't necessary, but generally, devices that use reflective materials to focus sunlight result in a greater temperature increase.

Evacuated Tube Collectors

This type of collector features rows of glass tubes placed parallel to each other with a vacuum between them that insulates the tubes and helps hold on to the heat. The tubes are also transparent and covered with a coating. Inside each tube is an absorber with liquid inside it. When light from the sun hits the tube and its radiation is absorbed by the absorber, the liquid inside is heated. Because of the vacuum between the tubes, this liquid can be heated to high temperatures, up to 175°C (350°F). Though the evacuated tube collectors can achieve high temperatures, they are more fragile than other types of solar collectors and more expensive.

Flat Plate Collectors

The most common type of energy collector, the flat plate collector, is a rectangular-shaped box that is put on the roof of the home or building where the solar water heating system is located. Inside the box is a thin absorber sheet, usually black in color and made of either copper or aluminum. Behind the sheet is a tubing system in the form of a grid or coils. The collector and tubing system are put inside an insulated casing. The cover is usually glass and transparent. This glass is often black or a dark color that draws in the sunlight.

As the sun shines, the heat builds up in the collector and heats the fluid that is inside the tubes. If it is water, it is heated and passes through a storage tank. If the fluid inside is antifreeze, the water is heated by circulating the heated solution through a tube inside the storage tank in which the water is located.

Line Focus Collectors

Line focus collectors (sometimes known as parabolic troughs) use highly reflective materials to collect and concentrate the heat energy from solar radiation. These collectors are composed of parabolically shaped reflective sections connected into a long trough. A pipe that carries water is placed in the center of this trough so that sunlight collected by the reflective material is focused onto the pipe, heating the contents. These are high-powered collectors and are

thus generally used to generate steam for solar thermal power plants and are not used in residential applications. These troughs can be extremely effective in generating heat from the Sun, particularly those that can pivot, tracking the Sun in the sky to ensure maximum sunlight collection.

Point Focus Collectors

Point focus collectors are large parabolic dishes composed of some reflective material that focus the Sun's energy onto a single point. Although effective at collecting sunlight, the point focus collectors must actively track the Sun across the sky to be of any value. These dishes can work alone or be combined into an array to gather even more energy from the Sun.

Point focus collectors and similar apparatuses can also be utilized to concentrate solar energy for use with concentrated photovoltaics. In this case, instead of producing heat, the energy of the Sun is converted directly into electricity with high efficiency photovoltaic cells designed specifically to harness concentrated solar energy.

Solar Energy

Solar energy is energy from the Sun, and in terms of alternative energy, *solar energy* refers to the energy that is harnessed from solar radiation, using the radiant light and heat from the Sun for practical purposes. The term solar power either is used synonymously with solar energy or is used more specifically to refer to the conversion of sunlight into electricity. Solar energy can be harnessed at different levels around the world, mostly depending on distance from the equator.

The Sun is most prominent source of energy in the solar system. The source of solar energy is the process of thermonuclear fusion in the core of the Sun. This energy is radiated from sun in all directions, and a fraction of this energy reaches to the earth. The outer visible layer of the Sun (the photosphere) has a temperature on the order of 6,000°C (10,800°F). Above the photosphere, there is a transparent layer of gases known as chromospheres. The light emitted by the chromospheres is of short wave length. Finally, there is the corona. The corona is the outer part of the atmosphere of the Sun – in this region, the prominence appears. Prominence is immense clouds of glowing gas that erupt from upper chromospheres. The corona can only be seen during total solar eclipse.

The Earth receives the solar energy in the form of solar radiation. These radiations are comprised of ultraviolet, visible, and infrared radiation. The amount of solar radiation that reaches any given location is dependent on several factors like geographic location, time of day, season, land scope, and local weather. Because the Earth is round, the Sun rays strike the Earth's surface at different angles ranging from 0 to 90°. When the rays of the Sun are vertical, the Earth receives the maximum possible energy.

Generally, almost all renewable energies, notably excluding geothermal energy and tidal energy, derive the energy from the sun. For example, winds blow partly because of absorption of solar radiation by the atmosphere of the Earth. Solar energy radiant light and heat from the Sun are harnessed using a range of ever-evolving technologies such as solar heating, solar photovoltaics, solar thermal electricity, solar architecture, and artificial photosynthesis.

There are many technologies for harnessing solar energy within these broad classifications: (i) active solar energy, (ii) passive solar energy, (iii) direct solar energy, and (iv) indirect solar energy.

Active solar energy systems use electrical and mechanical components such as tracking mechanisms, pumps, and fans to capture sunlight and process it into usable outputs such as heating, lighting, or electricity. On the other hand, passive solar systems use non-mechanical techniques to control the capture of sunlight and distribute this energy into usable outputs such as heating, lighting, cooling, or ventilation. These techniques include selecting materials with favorable thermal properties to absorb and retain energy, designing spaces that naturally circulate air to transfer energy and referencing the position of a building to the Sun to enhance energy capture. In some cases, passive solar devices can have mechanical movement with the important distinction that this movement is automatic and directly powered by the Sun.

Direct solar energy generally refers to technologies or effects that involve a single-step conversion of sunlight that results in a usable form of energy, while indirect solar energy generally refers to the generation of energy using technologies or effects that involve multiple-step transformations of sunlight that eventually result in a usable form of energy.

Collecting solar radiation and converting it into electricity – the production of solar power – can be achieved in two ways which are (i) directly using photovoltaic devices (PV devices, also referred to as solar cells), or (ii) indirectly using solar thermal/electric power plants. The first method involves grouping individual photovoltaic cells into panels and arraying panels, ranging from small cells to power watches and calculators to those that power single homes to those that produce electricity in power plants covering many acres. The second way uses concentrated solar power (CSP), whereby lenses or mirrors to concentrate a large area of sunlight, or solar thermal energy, onto a small area. Electrical power is produced when the concentrated light is converted to heat, which drives a heat engine (usually a steam turbine) connected to an electrical power generator or powers a thermochemical reaction.

The main benefits of solar energy are: (i) solar energy systems do not produce air pollutants or carbon-dioxide, and (ii) when located on buildings, they have minimal impact on the environment. However, the limitations are (i) the amount of sunlight that arrives at the surface of the Earth is not constant, and it varies depending on location, time of day, time of year, and weather conditions and (ii) the Sun does not deliver a constant amount of energy to any one place at any one time; a large surface area is required to collect the energy at a useful rate. This second limitation can be overcome by the use of storage batteries that preserve the stored energy until required. In fact, solar energy is a renewable resource and there is no limit to its renewability, at least not until the Sun burns itself out billions of years from now. Solar energy also does not contribute to pollution and thus is considered a “clean” energy source. Using it produces no greenhouse gases and thus does not contribute to global climate change.

However, a disadvantage is that solar technology is not available on demand in every location on the Earth. Heavy cloud cover can limit the use of some solar energy systems. Some systems cannot be used at all if direct sunlight is not available. In most areas of the world, only low-power solar energy applications can be used because of the lack of direct sunlight. Also, for large-scale projects such as solar power towers and solar furnaces, or even smaller-scale projects such as solar ponds, dish systems, and trough systems, large areas of land are needed. In the desert, where a number of these systems are currently located, the solar technology that is put there to capture the intense sunshine is considered unsightly by some people.

Also, solar energy can have both positive and negative effects on the environment. On the positive side, most solar technologies are environmentally friendly and (i) do not pollute the atmosphere by emitting greenhouse gases, (ii) do not produce radioactive waste as occurs in nuclear reactors, and (iii) do not contribute to global climate change or acid rain. Most solar energy systems are silent or quiet when they operate, which decreases noise pollution.

The benefits of solar energy systems include the potential in terms of energy hitting the Earth, the low environmental impact, and the lack of producing carbon dioxide and air pollutants. Limitations preventing the large-scale implementation of solar-powered energy generation is the inefficiency of current solar technology and the cost. In addition, the amount of sunlight varies depending on weather conditions, location, time of day, and time of year, and the need for a large surface to collect the energy, since it does not deliver concentrated energy at any one place.

See also: Photovoltaic Cells, Solar Energy – Active, Solar Energy – Passive, Steam Turbine.

Solar Energy – Active

Active solar energy systems include solar collectors (also known as solar panels), which are primarily used on solar hot water heaters; photovoltaic (PV) cells, which make electricity; and concentrated solar power systems (also known as solar thermal systems), which also make electricity but on a larger scale than photovoltaic cells.

Solar collectors are used primarily to capture solar energy for use in solar hot water heaters. However, they can also be used to provide heat in a building and even to make the energy to cool a building. While not all solar collectors are used in active solar energy systems, it is more common for solar collectors to be used in an active system than a passive system.

Photovoltaic cells convert sunlight directly into electricity inside the cell. They are more adaptable than many other types of solar energy technology. In addition to powering satellites, photovoltaic cells can be put on buildings to provide electricity for any number of uses and do not require direct sun to convert sunlight into electricity.

There are at least five types of concentrated solar power systems that focus the Sun's power to make electricity on a larger scale than photovoltaic cells and include (i) solar ponds, (ii) parabolic trough systems, (iii) dish systems and dish-engine systems, (iv) solar power towers, and (v) solar furnaces. Mirrors or other reflective devices draw in as

much sunlight as possible to these systems. They often track the Sun as it moves through the sky in order to capture the most sunlight.

Concentrated solar power systems usually heat water, or another fluid that is connected to a source of water, to make steam. The steam is used to drive turbines that create electricity. Concentrated solar power systems are primarily used for industrial applications and to make electricity for consumers and businesses on a wide scale.

Solar Energy – Passive

Passive solar systems are primarily concerned with the design of buildings, homes, and lighting. Passive solar design focuses on the placement of the home or building and on windows, ventilation, and insulation to cut down on the need for electricity by using the Sun. The home or building is designed to maximize the potential of solar energy for heating and cooling. In northern countries where sunshine is not as strong as it is in locations to the south, passive solar heating is one of the easiest forms of solar technology to use.

One important form of passive solar design is known as daylighting which involves the placement and design of windows used to encourage natural sunlight to light the inside of a building instead of electric lights. Daylighting helps cut down on lighting costs, and many experts believe that exposure to natural rather than artificial light sources provides health benefits to humans. Another type of passive solar system is the transpired solar collector. This is a relatively new passive solar technology made of dark perforated metal. Transpired solar collectors are used to heat buildings by heating the air. They can also cool buildings in summertime.

There are five basic types of passive solar design systems: (i) the direct gain type, (ii) thermal storage, (iii) solar greenhouse, (iv) roof pond, and the convective loop.

The direct gain technology is the simplest type of passive solar design. In this system, a large number of windows in a building are set up to face south (in the Northern Hemisphere). The glass is usually double-paned or even triple-paned. That is, the glass consists of two to three panes of glass with a pocket of air in between each pane. Each pane is sealed inside one frame. Materials that can absorb and store the Sun's heat can be incorporated into the floors and walls that are hit by the Sun. These floors and walls release the heat at night when it is needed the most to heat the building.

The thermal storage technology is similar to the direct gain technology. In this system, there is also a large wall oriented to the south in the Northern Hemisphere. This wall is placed behind double-glazed windows so that it can absorb sunlight. In some of these thermal storage systems, the wall contains a storage medium such as masonry or perhaps water. The solar energy that is collected is stored during daylight hours so that it can be released when there is no Sun.

The solar greenhouse technology is also known as the sunspace technology which is a combination of both direct gain and thermal storage but are located in a greenhouse. The wall of the thermal storage system is placed next to the greenhouse and the home to which it is attached. This system primarily heats the greenhouse but also can provide heat to the house itself.

As the name implies, the roof pond technology consists of ponds of water placed on a roof which are exposed to the Sun, collect the radiation from the Sun, and store it. The heat that is produced is controlled by insulating panels that are movable. During the winter, these panels are open during daylight hours so that sunlight can be collected. During nighttime hours, the panels are closed so that little or no heat is lost. The heat that is collected is released into the building to warm it. During the summer, roof ponds are used in the opposite way. The panels are closed during the day to block the heat of the sun. At night, they are opened to allow cooling of the building.

The convective loop technology is also known as a natural convective loop technology in which a collector is located below the building's living space. The hot air that is created from solar energy rises to heat this living space when needed.

Daylighting, also known as passive lighting, is a form of passive solar design and involves the use of sunlight to light up the inside of a building. Daylighting can fully replace electric lights, or it can be used to cut down on electrical costs by supplementing electrical lighting already being used and can also be used to heat a building.

Daylighting primarily occurs through a building's windows, though other kinds of openings on buildings, such as skylights, can also be used. The windows are often large and, in the Northern Hemisphere, face south. Buildings and homes that use daylighting have specific placement and spacing of windows. For example, windows that are higher up on a wall distribute sunlight better. Windows called clerestory windows (a row of windows located at the top of a wall, near the roof) are an important part of daylighting in museums and churches. Skylights, when combined with sensors and other lighting elements, can ensure that lighting inside a building stays even.

Windows used in daylighting absorb sunlight and release it slowly to light up a building. One way to regulate the amount of sunlight and/or heat is through window shades or curtains that are insulating. Light shelves can also be used. They are placed so that the sunlight drawn in by the windows is reflected and lights a room from top to bottom. These shelves can bring natural light deeper into a room.

Chemical compounds in windows for daylighting can be made part of window glass or placed between the panes of double- and triple-paned windows. These compounds can boost how much solar energy a window can store. They can also increase the insulating capacity of windows. In addition, coatings and glazing on the windows can control the amount of light or heat. The heating effect of daylighting can be increased by window coatings that are antireflective. Some window coatings can carry an electric current that can moderate how much light or heat is let in based on current weather conditions. One type of glazing can allow a measured amount of light to pass through a window while keeping heat out.

In daylighting systems where natural light is used with electrical lighting, there is the need for a control system. This control system regulates the amount of electric light used based on how much daylighting is available. The types of controls include photocell sensors, infrared receivers, occupant sensors, dimming control systems, and wall-station controls. Building materials and interior design can enhance the effectiveness of daylighting. Walls that are white or brightly colored reflect the light that is drawn inside. In office buildings, cubicle walls kept under a certain height will allow the sunlight to spread over the office.

As daylighting provides light during the day, the amount of heat gain from electric lighting is reduced significantly. Daylighting also makes homes and buildings less gloomy. However, homes and buildings that use daylighting often have to deal with issues such as heat and glare. If the natural lighting is not regulated, the system is not well-designed, or the correct type of window for the local environment is not used, homes and buildings can become hotter than they would were daylighting not used. Daylighting can potentially increase cooling costs during the summer because there is more natural light inside. Daylighting will not work everywhere because there is not enough sunshine in some locations.

Daylighting is difficult to incorporate into buildings that have already been constructed. Even if daylighting is built into a new building, the controls needed to regulate the natural light and electric lights are expensive and require a significant investment. After the system is installed, it must be operated and maintained. People must be trained to deal with the sensors and computer systems that come with many daylighting systems.

Solar Furnace

A solar furnace, in the same manner as a solar power tower, uses mirrors to concentrate sunlight onto one point to achieve high temperatures. The solar energy is collected from over a wide area. Solar furnaces can create higher temperatures than solar towers. There are several types of solar furnaces, each of which produces a different wattage of power.

The best known solar furnace is called a high-flux solar furnace which uses just one flat mirror or heliostat that is large in size and tracks the Sun to ensure the greatest reflection of sunlight onto the primary concentrator. The concentrator consists of twenty-five or so individual curved mirrors. These mirrors focus the light, called a solar flux, at a target inside the building.

The light from the concentrator is focused on a circle or target inside the furnace. The focused beam of light created by the concentrator is much, much stronger than normal sunlight. At its focal point, it can produce the energy of 2,500 suns. There can also be a reflective secondary concentrator added to the focus. The equivalent of up 20,000 suns can then be produced. When a refractive concentrator is added to the system to focus even more light on the

beam, the intensity can equal an amazing 50,000 suns. Temperatures rise very rapidly in a solar furnace, more than 1,000°C (1,830°F) per second. The power level inside the furnace is adjustable by a device called an attenuator, which works like pulling down blinds over a window.

A solar furnace is primarily used to generate heat or steam to make electricity and for industrial use. Steam created by a solar furnace can be used to run generators and industrial equipment. An advantage of using solar-created heat in such industrial processes is that the heat is clean, meaning that it produces no harmful emissions.

Solar Furnace – The Sun

Hydrogen and helium are by far the most common elements in the universe and together account for approximately 98% of all known matter. There is no significant amount of hydrogen or helium in the gaseous state on the Earth because the gravity of small planets is too weak to keep these light atoms attached; they simply escape into outer space. All of the Earth's hydrogen is combined with oxygen as water, with carbon as hydrocarbons, or with other elements in the rocks.

However, the Sun, whose gravity is much stronger, consists almost entirely of hydrogen. The presence of hydrogen in the Sun and the stars can be measured directly from spectroscopic observations since every atom emits light with characteristic *wavelengths* (or colors) that uniquely identify it.

Although there is plenty of hydrogen in the Sun for nuclear fusion, the conditions are such the fusion occurs. The temperature and density of the Sun can be determined by a combination of experimental observations using spectroscopy and by theoretical calculations. The most likely fusion reactions can be deduced from studies of nuclear reactions in the laboratory, using particle accelerators. The energy release in the Sun involves the conversion of four protons into a helium nucleus. However, this does not happen in a single step. First, two protons combine to form a nucleus of the heavy isotope of hydrogen (deuterium, hydrogen-2 or D_2). The deuterium nucleus then combines with another proton to form the light helium isotope (helium-3). Finally two helium-3 nuclei combine to form helium-4, releasing two protons in the process. Overall, four protons are converted into one helium nucleus (Figure S-2) and. As a result, energy is released because the helium nucleus has slightly less mass than the original four protons from which it was formed.

Figure S-2 The reactions that convert hydrogen to helium in the sun.

The total amount of energy released for each conversion of four hydrogen nuclei into a helium nucleus is approximately 10 million times more than is produced by the chemical reaction when hydrogen combines with oxygen and burns to form water. This enormous difference between the energy released by nuclear reactions compared to chemical reactions explains why fusion can sustain the Sun for billions of years.

The energy has to be transported from the Sun's interior core to the surface. This is quite a slow process, and it takes approximately one million years for the energy to get out. The surface of the Sun is cooler than the core, and the energy is radiated into space as the heat and light that can be observed directly. Under standard conditions, the solar power falling on the Earth is approximately 1.4 kilowatts per square meter (1.4 kW m^{-2}). The first stage of the reactions just described is a weak interaction. The process is slow, and this sets the pace for the conversion to helium. It takes many hundreds of millions of years for two protons to fuse together. This turns out to be rather fortunate. If the fusion reaction took place too quickly, then the Sun would have burned out long before life on Earth had a chance to evolve. From the knowledge of the nuclear reaction rates and of the amount of initial hydrogen, it is estimated that the time to use up all the hydrogen is approximately 10 billion years. From the radioactive dating of meteorites, it is estimated that the age of the solar system is 4.6 billion years. Assuming the Sun is the same age as the meteorites, then it is approximately halfway through its life cycle. For comparison, the most recent estimate of the age of the universe is approximately 13.7 billion years.

The proton-proton reaction tends to dominate in stars that are the size of the Sun or smaller. However, in larger stars, there is another reaction cycle, involving reactions with a carbon nucleus, by which protons can be converted into helium nuclei.

Solar Pond

A solar pond is a large, controlled body of water that collects and stores solar energy. Solar ponds do not use tracking systems such as mirrors, nor do they concentrate the Sun's rays like many other solar energy technologies.

There are two types of convection solar ponds. (Convection is a process in which a fluid such as water circulates, and in so doing, the circulation causes a transfer of heat.) One is called a salt-gradient pond. At the very bottom of the pond is a dark layer that can absorb heat. This is usually a liner made of butyl rubber or other dark material. In addition to helping the water absorb the heat, it helps protect the nearby soil and groundwater from being contaminated by the saltwater from the solar pond.

In the pond, there is a significant amount of salt located near the bottom. The types of salt commonly used are sodium chloride (NaCl) or magnesium chloride (MgCl_2). The water is saturated (filled entirely) or almost saturated with salt. The closer to the surface, the less salt is found in the water. At the very top of the pond is a layer of freshwater (that is, water without salt). This change in saltiness forms layers in the pond. The gradual change in the amount of salt is called a salt-density gradient.

The layers of saltwater stop the natural tendency of hot water to rise to the surface. Thus, the water that is heated by the Sun stays at the bottom of a solar pond. The layers that are close to the surface remain cool. There is a significant temperature difference between the top and the bottom of a solar pond, though some heat can be stored on every layer. Temperatures as high as 82 to 93°C (179 to 199°F) can be found at the bottom. The heat is extracted by a heat exchanger at the bottom of the pond. This heat energy can power an engine, provide space heating, or produce electricity via a low-pressure steam turbine. The heated saltwater can be pumped to the location where the heat is needed. After the heat is used, the water can be returned to the solar pond and heated again.

The second type of convection pond is a membrane pond. A membrane pond is similar to the salt-gradient pond except the layers of water are physically divided. They are separated by membranes that are thin and transparent. The separation of layers physically prevents convection (circulating movement). With a membrane pond, the heat that is created is also removed from the bottom layer of the pond as in a salt-gradient pond.

There are also two types of non-convection ponds. One is called a shallow solar pond. This pond has no saltwater. Pure freshwater is kept inside a large bag. The bag allows convection to take place but limits the amount of water that can be evaporated. At the bottom of the bag is a black area. Foam insulation can also be found near the bottom. On top of the bag are two types of glazing which are typically sheets of plastic or glass.

In a shallow solar pond, the sunshine heats the bag and the water inside during the day. The heat energy is extracted at night. The heated water is pumped into a large heat storage tank. This process can be difficult because heat loss is possible. The problems with heat loss have meant that shallow solar ponds have not been fully developed as a technology.

Solar Power

Solar power is often projected to be a potentially attractive alternative to fossil fuels. There are a number of special applications where solar power can be attractive, but for fundamental technological reasons, it is unlikely that it will be the ultimate solution for the electricity problems in various countries/regions.

Solar radiation may be converted directly into electricity by solar cells (photovoltaic cells). In such cells, a small electric voltage is generated when light strikes the junction between a metal and a semiconductor (such as silicon) or the junction between two different semiconductors.

There are two main advantages of producing electricity from the Sun. First, the source of energy is clearly renewable and free. Second, neither CO₂ nor other harmful emissions are produced during the energy conversion process.

In this sense, solar power is attractive environmentally. The disadvantages of solar energy are similar to those of wind. First, the Sun obviously shines brightly only during periods of cloud-free daytime. Consequently, producing base load power is not possible since there is no simple way to store excess energy during the day for use at night. Second, the Sun's intensity is low compared to that in a coal furnace.

Therefore, a large area of solar cells is required to produce a significant amount of power. For example, an area of approximately 50 square miles would have to be covered by solar panels to provide the 2.4 GW required by Boston. Recall that the area of Boston is also approximately 50 square miles so that the useful measure of energy for solar power can be produced.

Thus, solar power faces some challenges if it is to be used to produce large quantities of electricity. There are other more attractive uses, such as for residential and some commercial heating.

See also: Photovoltaic Cells, Photovoltaics.

Solar Tower

A solar tower (also known as a power tower, a central receiver, or a heliostat mirror power plant) uses solar energy to generate enough power to provide electricity over a large area. In this system, the Sun's power is collected by a large field of flat, movable mirrors. Sometimes, there are thousands of mirrors. The mirrors, called heliostats, move so they can track the Sun. They are focused on one single, fixed receiver that is located on top of a tall, central tower. Temperatures can be produced from 550 to 1,500°C (1,020 to 2,730°F) at the receiver.

The receiver collects all the energy and heat into a heat-transfer fluid that is flowing through it. In early power towers, this fluid was plain water. However, more recent models usually use molten salt, though liquid sodium, nitrate salt, and oil are also used. The heat energy held in the salt is used to boil water and make steam. This steam is used to generate electricity in a steam generator, usually located at the foot of the tower.

Molten salt can act as an efficient thermal storage medium for the heat collected in the solar tower. The heat can be stored for many hours or several days in this fashion. This storage medium is important. It allows the solar towers to be operational for up to 65% of the year. The rest of the time, a backup fuel source is used. When there is no energy storage medium, solar towers can only be used for approximately 25% of the year.

Solid Bed Adsorption

The solid bed adsorption process uses adsorbents that have the capability to adsorb high-boiling hydrocarbon derivatives from gas streams. The adsorbent may be silica gel or activated charcoal. Activated alumina cannot be used in the presence of high-boiling hydrocarbon derivatives, which foul the adsorbent.

The design of an adsorbent-based system for high-boiling hydrocarbon removal is more complicated than that of a system for the removal of water only. For instance, different grades of adsorbent may be required, and the system must also be designed to accommodate the adsorption of more than one component.

The adsorption process is continuous with respect to the gas but cyclical with respect to the adsorbent bed because the latter must be regenerated when it becomes saturated with condensate. Regeneration is accomplished by passing heated recycle gas through the bed. The condensate is recovered from the regeneration gas by cooling, condensation, and phase separation. To recover a large fraction of the hydrocarbon derivatives, while limiting the volume of adsorbent, it is preferable to use a relatively short cycle time, approximately one hour. In practice, this cycle time may vary within a fairly wide interval, between twenty minutes and several hours, depending on the quality of the hydrocarbon gas.

This process is appropriate for relatively low concentrations of high-boiling hydrocarbon derivatives. It can be also appropriate if the gas is at a high pressure, close to the cricondenbar. In this case, refrigeration processes become ineffective and separation by adsorption may offer the only way to obtain the required specifications.

The adsorption processes are easy to start up and to operate at high turn-down (changes in throughput), and so are useful for variable and on-stream and off-stream operations.

Solid Desiccant Dehydration

A solid desiccant is a hygroscopic solid material that is used to induce or sustain a state of dryness (desiccation) in its vicinity; it is the opposite of a humectant. Desiccants for specialized purposes may be in forms other than solid, and may work through other principles, such as chemical bonding of water molecules. They are commonly encountered in foods to retain crispness. Industrially, desiccants are widely used to control the level of water in gas streams.

Although some desiccants are chemically inert, others are extremely reactive and require specialized handling techniques. The most common desiccant is silica (SiO_2), an otherwise inert, nontoxic, water-insoluble white solid. Tens of thousands of tons are produced annually for this purpose. Other common desiccants include activated charcoal, calcium sulfate (CaSO_4), calcium chloride (CaCl_2), and molecular sieves (typically a zeolite derivative).

Some desiccants are only suitable for dehydrating the gas while others are capable of performing both dehydration and removal of high-boiling hydrocarbon components. The selection of proper desiccant for a given application is a complex problem. For solid desiccants used in gas dehydration, the following properties are desirable: (i) high adsorption capacity at equilibrium, which lowers the required adsorbent volume, allowing for the use of smaller vessels with reduced capital expenditures and reduced heat input for regeneration, (ii) high selectivity, which minimizes the undesirable removal of valuable components and reduces overall operating expenses, (iii) easy regeneration in which the relatively low regeneration temperature minimizes overall energy requirements and operating expenses, (iv) low pressure drop, (v) good mechanical properties (such as high crush strength, low attrition, low dust formation, and high stability against aging) which lower the overall maintenance requirements by reducing the frequency of adsorbent change out and minimizing downtime-related losses in production, and (vi) cheap, non-corrosive, non-toxic, chemically inert, high bulk density and no significant volume changes upon adsorption and desorption of water.

The most common commercial desiccants used in dry-bed dehydrators are molecular sieves and silica gel. However, a molecular sieve is the most versatile adsorbent because it can be manufactured for a specific pore size, depending on the application. The sieve should be (i) capable of dehydration to less than 1 ppm water content, (ii) the overwhelming choice for dehydration prior to cryogenic processes (especially true for LNG), and (iii) excellent for hydrogen sulfide removal, carbon dioxide removal, dehydration, high temperature dehydration, high-boiling hydrocarbon liquids, and highly selective removal. Molecular sieves, however, are more expensive than silica gel, but offer greater dehydration and require higher temperatures for regeneration, thus higher operating cost.

Silica gel is a widely used desiccant and is characterized by the following: (i) well suited for normal dehydration of natural gas, (ii) easily regenerated than molecular sieves, (iii) has high water capacity, where it can adsorb up to 45% of its own weight in water, (iv) costs less than molecular sieve. However, whatever the qualities, no desiccant is perfect or best for all applications. In some applications, the desiccant choice is determined primarily by economics. In other cases, the process conditions control the desiccant choice.

In the dehydration cycle, the wet inlet gas flows downward through the tower. The adsorbable components are adsorbed at rates dependent on their chemical nature, the size of their molecules, and the size of the pores in the solid material. The water molecules are adsorbed first in the top layers of the desiccant bed. Dry hydrocarbon gases are adsorbed throughout the bed. As the upper layers of desiccant become saturated with water, the water in the wet gas stream begins displacing the previously adsorbed hydrocarbon derivatives in the lower desiccant layers. Liquid hydrocarbon derivatives will also be absorbed and will fill pore spaces that would otherwise be available for water molecules. For each component in the inlet gas stream, there will be a section of bed depth, from top to bottom, where the desiccant is saturated with that component and where the desiccant below is just starting to adsorb that component.

The depth of bed from saturation to initial adsorption is known as the mass transfer zone (MTZ). This is simply a zone or section of the bed where a component is transferring its mass from the gas stream to the surface of the desiccant. As the flow of gas continues, the mass transfer zone moves downward through the bed and water displaces the previously adsorbed gases until finally the entire bed is saturated with water vapor. When the leading edge of the mass transfer zone reaches the end of the bed, breakthrough occurs. If the entire bed becomes completely saturated with water vapor, the outlet gas is just as wet as the inlet gas. Obviously, the towers must be switched from

the adsorption cycle to the regeneration cycle (heating and cooling) before the desiccant bed is completely saturated with water.

At any given time, at least one of the towers will be adsorbing while the other towers will be in the process of being heated or cooled to regenerate the desiccant. When a tower is switched to the regeneration cycle, some wet gas (that is, the inlet gas downstream of the inlet gas separator) is heated to temperatures of 230 to 315°C (450 to 600°F) in the high-temperature heater and routed to the tower to remove the previously adsorbed water. As the temperature within the tower is increased, the water captured within the pores of the desiccant turns to steam and is absorbed by the natural gas. This gas leaves the top of the tower and is cooled by the regeneration gas cooler. When the gas is cooled, the saturation level of water vapor is lowered significantly and water is condensed. The water is separated in the regeneration gas separator, and the cool, saturated regeneration gas is recycled to be dehydrated. This can be done by operating the dehydration tower at a lower pressure than the tower being regenerated or by recompressing the regeneration gas. Once the bed has been “dried” in this manner, it is necessary to flow cool gas through the tower to return it to normal operating temperatures (approximately 38 to 49°C, 100 to 120°F) before placing it back in service to dehydrate gas. The cooling gas could either be wet gas or gas that has already been dehydrated. If wet gas is used, it must be dehydrated after being used as cooling gas, where a hot tower will not sufficiently dehydrate the gas.

Bed switching is controlled by a time controller that performs switching operations at specified times in the cycle. The length of the different phases can vary considerably. Longer cycle times will require larger beds, but will increase the bed life. A typical two-bed cycle might have an eight-hour adsorption period with six hours of heating and two hours of cooling for regeneration. The 16 hours adsorption time for an adsorption unit with three beds, two beds in adsorption, and one bed in regeneration also makes a full cycle time of 24 hours.

Internal or external insulation for the adsorbers may be used. The main purpose of internal insulation is to reduce the total regeneration gas requirements and costs (invest cost however is higher). Internal insulation eliminates the need to heat and cool the steel walls of the adsorber vessel. Normally, a castable refractory lining is used for internal insulation. The refractory must be applied and properly cured to prevent liner cracks. Liner cracks will permit some of the wet gas to bypass the desiccant bed. Only a small amount of wet, bypassed gas is needed to cause freeze-up in cryogenic plants. Ledges installed every few feet along the vessel wall can help eliminate this problem.

Solid Emissions

The non-volatile oxidation products of the inorganic constituents of the fuel (e.g., sodium, potassium) are left as ash and contribute to the formation of corrosive deposits. When pulverized coal is used, a large proportion of the ash is carried out of the combustion chamber with the exhaust gas stream and has to be removed as completely as possible, usually by use of electrostatic precipitators. The removal of fly ash from combustion effluent streams is as important to the environment as the removal of sulfur oxides and nitrogen oxides. If not removed, the inorganic constituents and the organic constituents of the ash can cause serious environmental consequences, in addition to the solid particles acting as condensation nuclei and (catalytic) surfaces for the conversion of sulfur dioxide to the trioxide:

Because of its organic origin and its intimate co-mixture with mineral formations, coal contains a large number of elements in minor or trace quantities. Of the known non-transuranic elements, only a minority has not yet been found in coal. In regard to the behavior of trace elements in coal-fired power plants, the elements have been divided into two groups, those appearing mainly in the bottom ash (elements or oxides having lower volatility) and those appearing mainly in the fly ash (elements or oxides having higher volatility). For power plants using dry particulate collection devices, such as electrostatic precipitators, it was believed that the most volatile elements (such as mercury and selenium) could actually escape in the elemental state with the flue gas; wet scrubbers, however, were believed capable of removing most of the elements from the gas streams and transferring them to the liquid effluent. Essentially no particulates from coal combustion should be ejected into the atmosphere; all particulate streams

should be collected and either returned to the combustors, where they melt and are removed as slag, or are removed as fly ash. Any eventual dispersion of the elements present depends on the possibility of leaching. The concern, therefore, is to identify elements that may be occurring in the gaseous state. Among the trace elements present in coal with recognized toxic properties, high-volatility elements (beryllium, mercury, and lead) do not form gaseous-hydrides, will condense on cooling and likely will be almost completely removed by the aqueous condensates formed on gas cooling and/or purification. Arsenic, antimony, and selenium have lower volatility but can form gaseous hydrides, (covalent) hydrides such as arsine (AsH_3), stibine (SbH_3), and hydrogen selenide (H_2Se). These however, have stability characteristics that preclude their formation at the temperature and pressure prevailing in the oil/gas plant gasifiers.

Solid Fuels

Solid fuels are those fuels that are solid under ambient conditions and remain solid under mild heating. Thus, examples of solid fuels from biofuel feedstocks include wood and wood-derived charcoal and dried dung, particularly cow dung.

Compared to gaseous fuels and liquid fuels, solid fuels are often cheaper, easier to extract, more stable to transport, and in many places are more readily available. In particular, coal is utilized in the generation of electricity because it is less expensive and more powerful than its gaseous or liquid fuel counterparts. However, solid fuels are also heavier to transport, require more destructive methods to extract/burn, and often have higher carbon, nitrate, and sulfate emissions. With the exception of sustainable wood/biomass, solid fuel (such as peat or coal) is typically considered to be non-renewable because it requires thousands of years to form.

One widespread use of such fuels is in home cooking and heating. The biofuel may be burned on an open fireplace or in a special stove. The efficiency of this process may vary widely, from 10% for a well-made fire (even less if the fire is not made carefully) up to 40% for a custom-designed charcoal stove. Inefficient use of fuel is a cause of deforestation (though this is negligible compared to deliberate destruction to clear land for agricultural use), but more importantly, it means that more work has to be put into gathering fuel, thus the quality of cooking stoves has a direct influence on the viability of biofuels.

See also: Biofuel, Biomass, Solid Fuels from Waste.

Solid Fuels from Waste

The use of organic waste as cooking fuel in both rural and urban areas is not new. In seventeenth-century England, the rural poor often burned dried cow dung because of the acute shortage of wood fuel due to widespread deforestation. In some countries, cattle and buffalo dung is still used as relatively good cooking fuel. In the beginning of the nineteenth century, sawdust briquettes were made with binding materials such as tar, resins, and clay bind the small particles together. None of these processes attained great importance because of their relatively high costs compared to wood and conventional charcoal fuels.

Fuel briquettes emerged as a significant business enterprise in the 20th century. In the 1950s, several economic methods were developed to make briquettes without a binder. A multitude of factories throughout the world produced literally tens of millions of tons of usable and economic material that met the household and industrial energy needs. During the two World Wars, households in many European countries made their own briquettes from soaked waste paper and other combustible domestic waste using simple lever-operated presses. Modern industrial briquetting machines, although much larger and more complex, operate on the same principle.

Briquetting is undergoing resurgence, principally due to the convergence of three critical factors. First, the recent developments in briquette processing and binding have dramatically changed the economics of using fuel briquettes as an energy resource. Secondly, a shortage of fuel wood has become increasingly severe in most of the developing countries. Finally, there has been a steady increase by environmental concerns to address the problem of domestic and urban waste disposal, a dilemma that briquetting can help remedy.

See also: Bagasse Briquettes, Briquetting, Urban Waste Briquettes.

Solid Fuels from Wood

Burning wood as a fuel is the largest current use of wood-derived energy. Wood can be used in many forms as a solid fuel for cooking or heating, occasionally for steam engines, and for steam turbines that generate electricity.

The use of wood as a fuel source heat energy is as old as civilization itself. Historically, it was limited in use only by the distribution of technology required to make a spark. Wood heat is still common throughout much of the world, although it has been mainly replaced with coal, oil, or natural gas heating. Wood heating has been singled out as a serious health hazard in many regions of the world.

Early examples include the use of wood heat in tents. Fires were constructed on the ground, and a smoke hole in the top of the tent allowed the smoke to escape by convection. In permanent structures, hearths were constructed – surfaces of stone or another noncombustible material upon which a fire could be built. Smoke escaped through a smoke hole in the roof. The development of the chimney and the fireplace allowed for more effective exhaustion of the smoke. Masonry heaters or stoves went a step further by capturing much of the heat of the fire and exhaust in a large thermal mass, becoming much more efficient than a fireplace alone.

The particular form of wood fuel used depends upon (among other things) its source, quantity, and quality. Available forms include logs, bolts, blocks, firewood, stove-wood (often from split blocks), charcoal, chips, sheets, pellets, and sawdust. Sawmill waste and construction industry by-products also include various forms of lumber tailings.

See also: Fuel Wood, Logs and Wood Chips, Pellets and Briquettes, Steam Turbine.

Solid Waste

Solid waste is any garbage, refuse, sludge from a wastewater treatment plant, water supply treatment plant, or air pollution control facility and other discarded materials including solid, liquid, semi-solid, or contained gaseous material, resulting from industrial, commercial, mining and agricultural operations, and from community activities. Solid waste does not include solid or dissolved materials in domestic sewage, or solid or dissolved materials in irrigation return flows or industrial discharges. Also, a material cannot be a hazardous waste if it does not meet the definition of solid waste. Thus, wastes that are excluded from the definition of solid waste are not subject to hazardous waste regulation.

Generation of such wastes is typically originated from the residential community (i.e., municipal solid waste, MSW) or from commercial and light-industrial communities. Wastes generated from manufacturing activities of heavy-industrial and chemical industries involve wastes that are typically classified as hazardous wastes. As regulations continue to get stricter with decreasing land availability, alternative uses for the waste must be found in order to recover the residual heating values as well as to alleviate landfill-overburdening problems.

In landfill, the biodegradable components of the municipal solid waste decompose over time and emit methane – a very potent greenhouse gas that is known to be 23 times more potent than carbon dioxide as greenhouse gas. Therefore, the biodegradable components in municipal solid waste such as food and paper wastes that end up with going to landfills must be reduced in order to practice a good waste management plan. While refuse-derived fuel (RDF) is attractive from the sense of resource conservation as well as waste reduction, it also causes some serious concerns that the waste treatment for energy generation may result in new forms of environmental problems. Most of the processing difficulties arise from the heterogeneous and non-uniform nature of the waste feed itself which, in turn, generates a very widely varying spectrum of treated intermediates and by-products.

See also: Refuse-Derived Fuel, Municipal Solid Waste, Waste.

Solvent Extraction

Solvent extraction is a commonly used method to recover valuable materials or to remove contaminants from aqueous or non-aqueous waste streams. Leaching is solvent extraction applied to solid feeds. Solvent extraction is usually physical process in which selectivity is dependent on the relative solubility of the feedstock components in a chosen solvent.

The solvents used for solvent extraction can be either conventional liquids below their critical point or supercritical fluids operating at conditions above the critical point of the pure solvent. Most, if not all, of the separations that can be made with supercritical fluid solvents can also be made with liquid solvents. However, in some specific applications, there are enough operating benefits to favor supercritical fluids. Examples of these benefits are (i) lower operating temperature for heat-sensitive materials, (ii) ease of solvent recovery by pressure reduction or temperature increase, and (iii) faster phase separation due to lower viscosities and higher density differences between phases. The trend is toward increased use of supercritical fluid extraction solvents.

The interaction between solvent and solute can be purely physical intermolecular attraction, or there may be additional chemical forces superimposed on the physical attraction. These chemical forces increase the solvent selectivity for the materials that interact chemically with the solvent. They are the basis for extracting polar organics, metals, and ionic materials from aqueous streams. Examples of such interactions are ionic bonding, hydrogen bonding, and chemical complexing. The extraction processes using ionic interactions are frequently called liquid ion exchange.

In contrast to liquid extraction, which extracts a dissolved material from a liquid feed into a solvent, solvent precipitation works by dissolving an antisolvent into the liquid feed. This results in the formation of a second liquid or solid phase insoluble in the feed. The same fundamentals governing solubility of liquids in each other apply to both solvent extraction and solvent precipitation.

Solvent extraction is usually applied to liquid feeds. It is then called liquid-liquid extraction or supercritical fluid extraction. However, it can also be applied to solids and sludges to remove soluble liquid or solid impurities which permits both the recovery of valuable materials and the regeneration of solid adsorbents and catalysts. This type of extraction is usually referred to as leaching.

See also: Liquid-Liquid Extraction, Recovery Processes, Solvent Extraction., Supercritical Fluid Extraction.

Solvent Precipitation

Solvent precipitation differs from conventional liquid-liquid extraction in that the added solvent is not selectively dissolving the impurities but is changing the solvent properties of the feed so that the impurities can no longer stay in solution. The added solvent dissolves in the carrier of the waste contaminants and precipitates the impurities by generating a new carrier solvent which cannot hold the impurities in solution. The impurities then precipitate out of solution to form a second liquid phase or a solid phase.

Solvent precipitation techniques are based on the concept that high-molecular-weight and/or highly polar materials such as asphaltenes would normally not dissolve in oil. However, they are held in solution as a colloid by intermediate peptizing agents which interact strongly with the high-molecular-weight polar compounds. In the process, the most polar, highest-molecular-weight fractions precipitate first, followed by less polar and lower-molecular-weight fractions as the quantity of precipitating agent is increased. The precipitate can be either a solid or a liquid depending on the melting and solution properties of the precipitate.

Sorghum

Sorghum is an annual tropical grass with large genetic variation that is a crop with the potential for energy production. It is a genus of flowering plants in the grass family Poaceae. Seventeen of the 25 species are native to Australia with the range of some extending to Africa, Asia, and Central America as well as to islands in the Indian Ocean and the Pacific Ocean. One species is grown for grain, while many others are used as fodder plants, either cultivated in warm climates throughout the world or naturalized, in pasture lands.

Sweet sorghum has been selected for its sugar content and is normally grown for molasses production. Forage sorghum has been selected for high yields of reasonably good-quality animal feed. Sorghum varieties producing tall plants with large stems make the best candidates for biomass production. Both sweet and forage sorghum have a high potential for lodging. Lodging can result in harvest problems with ensuing loss of yield from both initial and ratoon crops.

This crop has been cultivated on a small scale in the past for production of table syrup, but other varieties can be grown for production of sugar. The most common types of sorghum species are those used for production of grain. Sweet sorghum can be considered as an energy crop, because it can be grown in all continents, in tropical, sub-tropical, temperate regions as well as in poor-quality soils. Sweet sorghum is a warm-season crop that matures earlier under high temperatures and short days. Sweet sorghum is an extraordinarily promising multifunctional crop not only for its high economic value but also for its capacity to provide a very wide range of renewable energy products, industrial commodities, food, and animal feed products. Sweet sorghum biomass is rich in readily fermentable sugars, and thus it can be considered as an excellent raw material for fermentative hydrogen production – hydrogen is an important commodity for the refining industry, and new sources are continually sought. Integrated production of several crops (sweet sorghum/sugar-cane/sweet sorghum corn/sweet sorghum/sweet potatoes) and simultaneous processing of the full crop components (starch, sugar, lignocellulosic) can improve the global economics of bioenergy schemes considerably in view of a viable production of bioethanol.

Sweet sorghum crops produce sugar syrups which could form the basis of fermentation processes for methane or ethanol production, and some of the forage types of the plant may be suitable for biomass production. Sweet sorghum has been grown in the southern United States for making syrup for many years and several widely adapted, high-yielding cultivars with high sugar concentrations are available. Sorghum production and harvesting can be completely mechanized with currently available equipment, and the juice can be fermented directly without enzyme treatment or cooking.

The economics of production and processing could offset the lower alcohol-yielding potential. An additional advantage to sorghum is that the crushed stalks make good-quality silage which could be used to winter cattle. The primary disadvantage of sorghum is that juice cannot be stored without refrigeration; therefore, use of sorghum as a feedstock is probably limited to a 2- or 3-month harvest period in the late summer and fall.

Sour Gas

Sour gas is any gas stream that contains significant amounts of hydrogen sulfide (H_2S). Natural gas is usually considered sour if there are more than 5.7 milligrams of hydrogen sulfide per cubic meter of natural gas, which is equivalent to approximately 4 ppm v/v. A gas stream that does not contain significant amounts of hydrogen sulfide is generally referred to as sweet gas.

Although the terms acid gas and sour gas are used interchangeably, strictly speaking, a sour gas is any gas that contains hydrogen sulfide in significant amounts, whereas an acid gas is any gas that contains significant amounts of acidic gases such as carbon dioxide (CO_2) or hydrogen sulfide. Thus, carbon dioxide by itself is an acid gas, but it is not a sour gas.

Before a raw gas stream containing hydrogen sulfide and/or carbon dioxide can be used, the raw gas must be treated to remove those impurities to acceptable levels, commonly by an amine gas treating process. The removed hydrogen sulfide is most often subsequently converted to by-product elemental sulfur in a Claus process, or it can be treated in a wet sulfuric acid process unit where the by-product is sulfuric acid.

Processes that are designed to remove mercaptans and/or hydrogen sulfide are commonly referred to as sweetening processes because they result in products which no longer have the sour, foul odors of mercaptans and hydrogen sulfide. Hydrogen sulfide is a toxic gas. It also places restrictions on the materials that can be used for piping and other equipment handling sour gas, as many metals are sensitive to sulfide stress cracking. The presence of hydrogen sulfide in gas causes lower-quality burning, and the production of sulfur dioxide, and so is regulated in commercially sold gas.

Soybeans

Soybeans (soyabeans) are a bushy, leguminous plant, *Glycine max*, native of South-East Asia that is grown for the beans, which are used widely in the food industry, for protein in cattle feed and for oil production.

Soybeans are the most commonly grown oil seed crop in the Southeastern United States and the easiest to grow and harvest. Yields are quite dependent on rainfall and various management factors including crop rotation and double-cropping with wheat. It is not particularly difficult to produce in excess of 3,000 kg/ha in a good year with an adapted cultivar. While soybeans produced less oil than several of the other crops that were tested, the high protein content of the oil seed meal makes it a valuable by-product. The crop also has the advantage of being a legume and thus requires no nitrogen fertilizer.

Oil (approximately 40% w/w) and protein (approximately 20% w/w) content account for the majority of dry soybeans. The remainder consists of 35% carbohydrate (approximately 35% w/w) and mineral constituents (approximately 35% w/w).

The principal soluble carbohydrates of mature soybeans are the disaccharide sucrose (range 2.5 to 8.2% w/w), the trisaccharide raffinose (0.1 to 1.0%) composed of one sucrose molecule connected to one molecule of galactose, and the tetra-saccharide stachyose (1.4 to 4.1%) composed of one sucrose molecule connected to two molecules of galactose.

The higher-molecular-weight insoluble carbohydrates in soybeans consist of the complex polysaccharides cellulose, hemicellulose, and pectin.

To extract soybean oil from seed, the soybeans are cracked, adjusted for moisture content, rolled into flakes, and solvent-extracted with commercial hexane. The oil is then refined, blended for different applications, and sometimes hydrogenated. Soybean oils, both liquid and partially hydrogenated, are exported abroad, sold as vegetable oil, or end up in a wide variety of processed foods. The remaining soybean husks are used mainly as animal feed.

Biodiesel from soybean oil can be used in diesel engines with little or no modifications. The transesterification process gives two products: biodiesel and glycerin (used to make soap).

As compared to normal diesel, soy biodiesel is better for the environment because it is made from renewable resources and has lower emissions compared to diesel fuel from crude oil. The use of biodiesel in a conventional diesel engine results in substantial reduction of unburned hydrocarbon derivatives, carbon monoxide, and soot. The use of biodiesel does not increase the carbon dioxide level in the atmosphere, since growing soybeans also consumes carbon dioxide. Biodiesel is also more biodegradable than conventional diesel, and lubrication tests have demonstrated the lubrication advantage of biodiesel.

See also: Biodiesel, Diesel Fuel, Transesterification.

SO_x

SO_x is the shortened version for the term *oxides of sulfur* which are emitted when a sulfur-containing fuel is combusted.

Sulfur oxides (SO_x) are compounds of sulfur and oxygen molecules. Sulfur dioxide (SO₂) is the predominant form found in the lower atmosphere. It is a colorless gas that has a pungent, unpleasant odor. Sulfur dioxide dissolves readily in water present in the atmosphere to form sulfurous acid (H₂SO₃). Approximately 30% of the sulfur dioxide in the atmosphere is converted to sulfate aerosol (acid aerosol), which is removed through wet or dry deposition processes. Sulfur trioxide (SO₃), another oxide of sulfur, is either emitted directly into the atmosphere or produced from sulfur dioxide and is rapidly converted to sulfuric acid (H₂SO₄).

When atmospheric pollutants such as sulfur dioxide and nitrogen oxides mix with water vapors in the air, they are converted to sulfurous acid:

In the gas phase, sulfur dioxide is oxidized by reaction with the hydroxyl radical via an intermolecular reaction:

In the presence of water, sulfur trioxide (SO₃) is converted rapidly to sulfuric acid:

Acid rain (acid deposition) can be classified as wet deposition such as acid rain, snow, sleet, and fog or dry deposition such as deposition as particulate matter even less than PM 2.5. The effects of acid rain can either be chronic or episodic. Chronic acidification is a long-term effect due to years of acid rain. Episodic acidification is due to heavy rain storms; it also occurs in spring as concentrated nitrate and sulfate in the lower layer of snow pack get released when snow melts. A second method of acid deposition is known as dry deposition. While wet deposition involves the precipitation of acids, dry deposition occurs when the acids are first transformed chemically into gases and salts, before falling under the influence of gravity back to Earth. Sulfur dioxide, for example, is deposited as a gas and as a salt.

See also: Acid Rain.

Specific Gravity

The specific gravity is the mass (or weight) of a unit volume of any substance at a specified temperature compared to the mass of an equal volume of pure water at a standard temperature. Substances with a specific gravity greater than one are denser than water, and so will sink in it, and those with a specific gravity of less than one are less dense than water, and so will float in it.

Specific gravity, SG, is expressed mathematically as:

$$\text{Specific gravity} = (\text{density of substance})/(\text{density of water})$$

Since the density of water varies with temperature and pressure, it is usual to refer specific gravity to the density at 4°C (39.2°F) and a normal pressure of 1 atmosphere. The given temperature and pressure are preferred because it is when water has its maximum density. In this case, the density of water is equal to 1,000 kg·m⁻³ in SI units (or 62.43 lb per cubic foot, 62.43 lb·ft⁻³ in the customary units of the United States). Given the specific gravity of a substance, its actual density can be calculated by inverting the above formula:

Density of the substance = specific gravity x (density of water)

Occasionally, a reference substance other than water is specified (for example, air), in which case specific gravity means density relative to that reference.

In addition, the specific gravity of gas can also be determined and is defined as:

$$\text{Specific gravity of gas} = M/M_{\text{air}}$$

M_{air} is the molecular weight of air, which is equal to 29. Once we can calculate the value of the molecular weight of the mixture, we can calculate the specific gravity of the mixture. For a gas mixture, the molecular weight can be calculated as:

$$M = \sum_{i=1}^n y_i M_i$$

M_i is the molecular weight of component i , y_i is the mole fraction of component i , and n is the total number of components.

Specific Heat

Specific heat is the quantity of heat required to raise a unit mass of material through one degree of temperature (ASTM D2766). Specific heats are extremely important engineering quantities in refinery practice because they are used in all calculations on heating and cooling petroleum products. Many measurements have been made on various hydrocarbon materials, but the data for most purposes may be summarized by the general equation:

$$C = 1/d (0.388 + 0.00045t)$$

C is the specific heat at t°F of an oil whose specific gravity 60/60°F is *d*; thus, specific heat increases with temperature and decreases with specific gravity.

Spontaneous Combustion

Spontaneous combustion is the self-ignition of carbonaceous material through oxidation under specific conditions. Different types of material in the tendency toward self-ignition. Spontaneous combustion is usually the culmination of several separate chemical and physical events. It is a question of degree and the correct order of reactions being in place.

In ordinary combustion, the material is deliberately heated to its ignition point to make it burn. During this process, many materials (especially hydrocarbon derivatives) undergo slow oxidation that, like the rapid oxidation of burning, releases heat. If the heat so released cannot escape, the temperature of the hydrocarbon rises until ignition takes place. Spontaneous combustion often occurs in piles of hydrocarbon-soaked (oily) rags and can constitute a serious fire hazard. Also, fires started by spontaneous combustion are caused by the following mechanisms: (i) spontaneous heating, (ii) pyrophoricity, and (iii) hypergolic reactions.

Spontaneous heating is the slow oxidation of an element or compound which causes the bulk temperature of the element or compound to rise without the addition of an external heat source. Spontaneous heating may be the result of direct oxidation of hydrocarbons (for example, oils and solvents), or it may occur because of the action of microorganisms in organic materials. Saturated hydrocarbon derivatives (such as alkane derivatives) do not have a tendency for spontaneous combustion, whereas unsaturated hydrocarbons do have a tendency for spontaneous combustion.

Pyrophoric substances are substances (or chemicals) that ignite instantly upon exposure to air (atmospheric oxygen). A pyrophoric substance may be a solid, liquid, or gas. Most materials are not pyrophoric unless they are in a very finely divided state. Although there are some pyrophoric liquids and gases, most pyrophoric materials are metals. Pyrophoricity is a special case of a hypergolic reaction because the oxidizing agent is restricted to atmospheric oxygen.

A *hypergolic reaction* describes the tendency of a material ability to spontaneously ignite or explode upon contact with any oxidizing agent. Some hydrocarbons are capable of spontaneous heating and ignition under proper conditions. Spontaneous heating of hydrocarbons usually involves a combustible liquid hydrocarbon in contact with combustible materials. An example of this would be combustible rags impregnated with oils or solvents. Whether or not spontaneous heating leads to ignition depends on several items: (i) the rate at which heat is generated and removed from the material being oxidized, (ii) the ignition temperature of the fibrous combustible material, hydrocarbon, or any gases liberated by oxidation, (iii) the specific area (cm²/g, defined below) of the hydrocarbon exposed to an oxidizer, and (iv) the amount of moisture present in the atmosphere and the fibrous material.

Spontaneous combustion may occur in piles of moist organic material where heat is generated in the early stages by the respiration of bacteria, molds, and microorganisms. High moisture content is required for vigorous activity, and heating is generally controlled by maintaining the moisture content below a predetermined level. This type of heating can only raise the material to the temperature range of 50 to 75°C (122 to 167°F), where the living organisms die.

Beyond this point, the oxidant of the material must take over if ignition is to occur. The existence of biological heating requires careful control of moisture, air supply, and nearby combustible or flammable materials. If a hot spot in a pile of organic material comes in contact with a highly flammable liquid or gas, a fire or explosion may

occur. Heat generated by biological action may also act as a catalyst for other reactions which occur only at elevated temperatures.

See also: Spontaneous Ignition.

Spontaneous Ignition

Spontaneous ignition is the ignition of a fuel under normal atmospheric conditions; usually induced by climatic conditions. Spontaneous ignition is a possible cause of unwanted fire and involves the ignition of a combustible material by its own heat of reaction without external heat or other source of ignition.

Two basic factors contribute to spontaneous heating and ignition: heat generation and heat dissipation. If heat generates faster than it dissipates, it accumulates, i.e., temperature increases. Of the many kinds of heat-generating reactions, oxidation is the most common. Practically all organic substances and some inorganic ones will oxidize if exposed to the atmosphere and produce heat. Usually, the rate of oxidation is slow. Only materials that are self-heating have a significant rate.

Spontaneous ignition is usually the culmination of several separate chemical events, although precise knowledge of the phenomenon is still somewhat incomplete but is gradually becoming known and there are means by which the liability of a coal to spontaneously ignite can be tested.

For example, exposure of a fuel to air will bring about not only loss of moisture but also oxidation. The latter process, often referred to as auto-oxidation or autoxidation, commences when the coal reacts with oxygen (of the atmosphere). Both processes result in an alteration of the properties of the material.

Sawdust and wood chips self-heat much more readily than solid wood; in general, fibrous and finely divided materials are more susceptible to spontaneous ignition. One reason is that a material in a finely divided state has a lower thermal conductivity than one in the solid state so that heat is accumulated more easily. Another is that any decrease in particle size results in increased surface area. An oxidation reaction takes place on the surface exposed to the air. Powdered metals such as aluminum and magnesium powders are much more easily ignited than solid metals.

Charcoal and carbon black are also susceptible to spontaneous ignition; the more finely divided the charcoal, the greater the hazard. Wood, when subjected to prolonged periods of heating and cooling cycles, may ignite spontaneously. The alternate heating and cooling processes may chemically decompose the wood to produce pyrophoric carbon, which oxidizes rapidly followed by ignition. Wood chips in huge piles, as at paper mills, are known to ignite spontaneously.

See also: Spontaneous Combustion.

Spray Tower

A spray tower consists of empty cylindrical or rectangular chambers in which the gas stream is contacted with liquid droplets generated by spray nozzles. A common form is a spray tower, in which the gas flows upward through a bank or successive banks of spray nozzles. Similar arrangements are sometimes used in spray chambers with horizontal gas flow. Such devices have low gas pressure drops, and all but a small part of the contacting power is derived from the liquid stream. The required contacting power is obtained from an appropriate combination of liquid pressure and flow rate.

Physical absorption depends on properties of the gas stream and liquid solvent, such as density and viscosity, as well as specific characteristics of the pollutant(s) in the gas and the liquid stream (e.g., diffusivity, equilibrium solubility). These properties are temperature dependent, and lower temperatures generally favor absorption of gases by the solvent. Absorption is also enhanced by greater contacting surface, higher liquid-gas ratios, and higher concentrations in the gas stream (EPA, 1991). Chemical absorption may be limited by the rate of reaction, although the rate-limiting step is typically the physical absorption rate, not the chemical reaction rate. Countercurrent packed towers are also used but, in some cases, they have a tendency to become plugged by collected particles or to scale when lime (CaO) or limestone (CaCO₃) scrubbing slurries are used.

Water is the most common solvent used to remove inorganic contaminants. Pollutant removal may be enhanced by manipulating the chemistry of the absorbing solution so that it reacts with the pollutant. An example of this is using caustic solution for acid-gas absorption instead of pure water as a solvent. Amphiphilic block copolymers dissolved in the water can be used to remove hydrophobic volatile organic compounds, which has much less affinity for water than hydrophilic volatile organic compounds. Used in flue gas desulfurization systems, spray tower scrubbers introduce a reagent slurry as atomized droplets through the spray nozzles at the top of, or in stages within the scrubber.

In the process, the gas (containing sulfur dioxide) enters at the bottom of the column and travels upward through the tower in a countercurrent flow, though horizontal spray towers which use a crosscurrent design also exist. In most cases, the sorbent is an alkaline slurry, commonly limestone (CaCO_3), slaked lime [$\text{Ca}(\text{OH})_2$], or a mixture of slaked lime and alkaline (typically potassium carbonate K_2CO_3 , or potassium bicarbonate, KHCO_3) fly ash, though many other sorbent processes exist. Absorption of sulfur dioxide is accomplished by the contact between the gas reagent slurry. The sulfur oxides react with the sorbent, forming a wet mixture of calcium sulfite (CaSO_3) and calcium sulfate (CaSO_4).

For horizontal flue gas desulfurization equipment process, the fresh slurry (composed of a recycle stream and a makeup stream) is often introduced at the last, or rear, stage of the absorber where the sulfur dioxide content of the gas stream is lowest. The slurry contacted in the last stage is pumped forward to the next stage. This way, the slurry flows countercurrent to the gas flow.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Spreading

Spreading is a form of dispersion in which the movement of chemical contaminants through the subsurface is complex and is difficult to predict since different types of chemicals react differently with soils, sediments, and other geologic materials and commonly travel along different flow paths and at different velocity. Chemicals released from a source area (typically on the surface) infiltrate (through solubility in water) into the subsurface and migrate downward by gravity as an aqueous solution through the vadose zone (the zone that extends from the top of the ground surface to the water table). When low permeability soil units are encountered, the contaminants in aqueous solution can also spread laterally along the permeability contrast.

Most chemical contaminants are introduced into the subsurface by percolation through soil strata, and the interactions between the soil and the chemical are important for assessing the fate and transport of the contaminant in the subsurface, especially in the groundwater system. Contaminants that are highly soluble, such as salts and any potentially ionic derivatives, can move readily from surface soil to saturated materials below the water table and often occurs during and after rainfall events. Those contaminants that may not be highly soluble may have considerably longer residence times in the surface strata (the soil zone). Some chemicals adsorb readily onto soil particles and slowly dissolve during precipitation events, resulting in migration into. Once below the water table, chemical contaminants are also subject to dispersion (mechanical mixing with uncontaminated water) and diffusion (dilution by concentration gradients). Many contaminants begin to spread immediately after entry into the environment.

See also: Absorption and Adsorption.

Stability and Instability

A fuel is a delicately balanced system insofar as the different fractions that contain hydrocarbon derivatives (saturates and aromatics) as well as heteroatom constituents. The heteroatom constituents tend to concentrate in the higher-molecular-weight fractions (the asphaltene constituents and resins). The nitrogen, oxygen, and sulfur species that are in near-neutral molecular locales will also occur in the saturate fraction and in the aromatics fraction, remembering that the nomenclature is not necessarily precise and that the composition of each fraction is a function of the separation process.

Instability (the formation of a separate or insoluble phase) usually occurs with the separation or precipitation of insoluble constituents. This may be caused by well stimulation, such as acidizing which involves a drastic shift in local chemical equilibria, pH, and liberation of carbon dioxide. It may also increase the concentration of some ions, such as iron, which will promote the formation of a sediment. Similarly, the separation of wax from paraffinic crude oil will also occur under certain conditions (some or defined, some are not) and cause problems during use by blocking the flow channels.

See also: Instability and Incompatibility.

Stabilization

Stabilization is the removal of relatively volatile constituents from a higher boiling fraction or product, or it is the production of a product which, to all intents and purposes, does not undergo any further reaction when exposed to the air.

The simplest stabilization process is a stripping process. Low-boiling naphtha from a crude tower, for example, may be pumped into the top of a tall, small-diameter fractional distillation tower operated under a pressure of 50-80 psi. Heat is introduced at the bottom of the tower by a steam reboiler. As the naphtha cascades down the tower, the light ends separate and pass up the tower to leave as an overhead product. Since reflux is not used, considerable amounts of liquid hydrocarbon derivatives pass overhead with the light ends.

An example of more precise stabilization can be seen in the handling of the mixture of hydrocarbon derivatives produced by cracking. The overhead from the atmospheric distillation tower that fractionates the cracked mixture consists of light ends and cracked naphtha with light ends dissolved in it. If the latter is pumped to the usual type of tank storage, the dissolved gases cause the naphtha to boil, with consequent loss of the gases and some of the liquid components. To prevent this, the naphtha and the gases dissolved in it are pumped to a stabilizer maintained under a pressure of approximately 100 psi and operated with reflux. This fractionating tower makes a cut between the highest boiling gaseous component (butane) and the lowest boiling liquid component (pentane). The bottom product is thus a liquid free of all gaseous components, including butane; hence, the fractionating tower is known as a debutanizer. The debutanizer bottoms (naphtha constituents) can be safely stored, whereas the overhead from the debutanizer contains the butane, propane, ethane, and methane fractions. The butane fraction, which consists of all the hydrocarbon derivatives containing four carbon atoms, is particularly needed to give easy starting characteristics to gasoline. It must be separated from the other gases and blended with motor gasoline in amounts that vary with the season: more in the winter and less in the summer. Separation of the butane fraction is effected by another distillation in a fractional distillation tower called a depropanizer, since its purpose is to separate propane and the lower-boiling gases from the butane fraction.

The depropanizer is similar to the debutanizer, except that it is smaller in diameter because of the smaller volume being distilled and is taller because of the larger number of trays required to make a sharp cut between the butane and propane fractions. Since the normally gaseous propane must exist as a liquid in the tower, a pressure of 200 psi is maintained. The bottom product, known as the butane fraction, stabilizer bottoms, or refinery casinghead, is a high-vapor-pressure material that must be stored in refrigerated tanks or pressure tanks. The depropanizer overhead, consisting of propane and lower-boiling gases, is used as a petrochemical feedstock or as a refinery fuel gas, depending on the composition.

Stack Gas

Stack gas is the product gas evolved during complete combustion of a fuel that is allowed to escape through a stack.

Combustion processes for heat and power generation and the incineration of household waste generate gaseous by-products that are not always adequate for the production of further products.

Flue gases from combustion facilities have a composition that is different from the composition of air because of high concentrations of the combustion products water (H_2O) and carbon dioxide (CO_2). More concern, however, goes to what is in these gases besides these bulk species, such as oxides of sulphur and nitrogen, fine dust,

trace elements such as mercury and nickel, and super-toxics such as dioxins. All of these compounds are actually unwanted by-products from a power plant or a waste incinerator, since the first has the objective to convert hydrocarbon fuels (C_xH_y) into carbon dioxide (CO_2), water (H_2O) plus heat and power, while the second aims at reducing a large volume of solid or liquid waste into a small amount of solid ashes plus, again, carbon dioxide and water from the combustion of the organic compounds. However, the fuel or waste materials that are combusted contain chemicals that are vaporized or converted chemically into gases that mix with the harmless gases water, carbon dioxide, oxygen, and nitrogen as, for example sulfur dioxide (SO_2), nitric oxide (NO), fly ash, and even hydrogen chloride when plastics (such as polyvinyl chloride) are combusted.

By means of a stack height, these gases (then known as stack gas(es)) can be dispersed into the atmosphere without much effect to the environment at short range. At the same time, the mere presence of a stack indicates that there must be reasons for actively transporting the gases away from the facilities that generate them. These reasons are that the temperature, and, more importantly, the composition of the gases are different from those of the ambient atmosphere at ground level. The formation of ground-level ozone from traffic exhaust gases during sunny summer days is a good example of what happens when large amounts of flue gases are released at ground level.

See also: Combustion.

Stack Gas Scrubbing

Most stack gas scrubbing processes are designed for sulfur dioxide removal; nitrogen oxides are controlled as far as possible by modification of combustion design and flame temperature regulation. However, processes for the removal of sulfur dioxide usually do remove some nitrogen oxides; particulate matter can be removed efficiently by commercially well-established electrostatic precipitators.

There are several processes for the removal of sulfur dioxide from stack gas, but scrubbing process utilizing limestone ($CaCO_3$) or lime [$Ca(OH)_2$] slurries have received more attention than other stack gas scrubbing processes. Attempts have been made to use dry limestone or dolomite ($CaCO_3 \cdot MgCO_3$) within the combustor as an *in situ* method for sulfur dioxide removal, thus eliminating the wet sludge from wet processes. This involves injection of dry carbonate mineral with the coal followed by recovery of the calcined product along with sulfite and sulfate salts:

The various solid products are removed by standard means, including cyclone separators and electrostatic precipitators.

Starch Crops

Starch (or *amylum*) is a polymeric carbohydrate consisting of numerous glucose units joined by glycosidic bonds called polymers.

The basic chemical formula of the starch molecule is $(C_6H_{10}O_5)_n$. Starch is a polysaccharide comprising glucose monomers joined in α 1,4 linkages. The simplest form of starch is the linear polymer amylose; amylopectin is the branched form. This polysaccharide is produced by most green plants as energy storage.

In starch crops, most of the six-carbon sugar units are linked together in long, branched chains (called starch). Yeast cannot use these chains to produce ethanol. The starch chains must be broken down into individual six-carbon units or groups of two units. The starch conversion process is relatively simple because the bonds in the starch chain can be broken in an inexpensive manner by the use of heat and enzymes, or by a mild acid solution.

From the standpoint of ethanol production, the long, branched chain arrangement of six-carbon sugar units in starch crops has advantages and disadvantages. The principal disadvantage is the additional equipment, labor, and energy costs associated with breaking down the chain so that the individual sugar units can be used by the yeast.

However, this cost is not large in relation to all of the other costs involved in ethanol production. The principal advantage in starch crops is the relative ease with which these crops can be stored, with minimal loss of the fermentable portion. Ease of storage is related to the fact that a conversion step is needed prior to fermentation: many microorganisms, including yeast, can utilize individual or small groups of sugar units, but not long chains. Some microorganisms present in the environment produce the enzymes needed to break up the chains, but unless certain conditions (such as moisture, temperature, and pH) are right, the rate of conversion is slow. When crops and other feeds are dried to approximately 12% moisture – the percentage at which most microorganisms cannot survive – the deterioration of starch and other valuable components (for example, protein and fats) is minimal. There are basically two subcategories of starch crops: grains (e.g., corn, sorghum, wheat, and barley) and tubers (e.g., potatoes and sweet potatoes). The production of beverage-grade ethanol from both types of starch crops is a well-established practice.

Much of the current agronomic research on optimizing the production of ethanol and livestock feed from agricultural crops is focused on unconventional sugar crops such as sweet sorghum. However, opportunities also exist for selecting new varieties of grains and tubers that produce more ethanol per acre. For example, when selecting a wheat variety, protein content is usually emphasized. However, for ethanol production, high starch content is desired. It is well known that wheat varieties with lower protein content and higher starch content usually produce more grain per acre and, consequently, produce more ethanol per acre.

Starches

Starches are complex carbohydrate polymers (polysaccharides). Starch (*amylum*) is a carbohydrate consisting of a large number of glucose units joined together by glycoside bonds. This polysaccharide is produced by all green plants as a means of storing energy store.

Representation of the Structure of Starch.

Pure starch is a white, tasteless, and odorless powder that is insoluble in cold water or alcohol. It consists of two types of molecules: the linear and helical amylose and the branched amylopectin. Depending on the plant, starch generally contains 20 to 25% amylose and 75 to 80% amylopectin. Glycogen, the glucose store of animals, is a more branched version of amylopectin.

Starch is processed to produce many of the sugars in processed foods. When dissolved in warm water, starch can be used as a thickening, stiffening, or gluing agent, giving wheat paste.

The starch grains generally provide cheaper ethanol feedstocks, and the conversion is less expensive because they can be stored more easily than most sugar crops, which often must be reduced to a form of syrup prior to the storage. Furthermore, grain distillation produces a by-product that can be used for protein meal in the animal feeds. Fermentation of starch from grains is somewhat more complex than sugars because the starch must first be converted to sugar and then to ethanol.

The simplified equations for the conversion of starch to ethanol can be written as:
Enzymatic hydrolysis of starch to sugars:

Fermentation of sugars to alcohol:

Steam-Air Gasifier

Most of the gasifiers that are applicable to use as a means of gasifying biomass can be operated on air rather than oxygen if a fuel rather than a synthesis gas is to be produced. In many cases, gasifiers developed specifically for gasification with air are being further developed for relatively pure oxygen feeds.

The gasifier itself is a pressurized fluidized bed system that operates at approximately 1,000°C (1,830°F). In one version of the gasifier, the crushed and dried coal is first devolatilized in a separate fluidized bed reactor. One purpose of the devolatilizing unit is to pretreat caking coals to prevent agglomeration and plugging in the gasifier fluidized bed. Simultaneous removal of sulfur gases by absorption into dolomite has also been tested. Some success has been had in operating the gasifier as a single stage unit without initial coal devolatilization, although bridging problems can arise in this mode. Advantages claimed for the Westinghouse gasifier include the capability of handling all ranks of coals and carbonaceous feedstocks with high carbon conversion, and the absence of tars and oils in the product gas.

Another elevated pressure, fluidized bed gasifier designed originally for steam/air operation is the U-Gas process developed by the Institute of Gas Technology. Operating temperatures are around 1,000°C (1,830°F), the gasifier is a vertical vessel with external cyclones for returning elutriated fines to the bed. A sloped grid at the bottom containing one or more inverted cones serves as the oxidant and steam distributor and an agglomerated ash outlet. Part of the fluidizing steam and oxidant flows through nozzles in the grid, and the remaining gas flows upward at high velocity through a discharge at the cone apex. High temperatures accompany the high velocities, and the ash particles soften and agglomerate, eventually becoming heavy enough to fall out of the bed. The fluidizing velocities are from 0.6 to 1.2 m/s, and the bed is approximately 45% ash. This system is said to produce high carbon conversion efficiencies comparable to slagging gasifiers.

See also: Gasification, Gasifiers.

Steam Explosion

Steam explosion is a pretreatment technology that is applied prior to the hydrolysis of lignocellulosic feedstocks to produce sugars and alcohols.

In the process, a lignocellulosic feedstock, such as wood chips, is heated with high-pressure saturated steam [160 to 260°C (320 to 500°F) 100 to 700 psi] for several seconds up to a few minutes. Then, the material is suddenly exposed for atmospheric pressure resulting in an explosive decompression. The process causes hemicellulose degradation and lignin transformation due to high temperature, thus increasing the potential of cellulose hydrolysis. Ninety percent efficiency of enzymatic hydrolysis has been achieved in 24 h for poplar chips, compared to 15% efficiency without pre-treatment.

The factors involved are residence time, temperature, chip size, and moisture content. Optimal solution is obtained by use of high temperature and short residence time (270°C 520°F, 1 minute) or by use of low temperature and long residence time [190°C (375°F), 10 minutes]. Addition of sulfuric acid can effectively improve enzymatic hydrolysis and lead to more complete removal of hemicellulose.

Steam Gasification

Steam gasification reaction is endothermic, i.e., requiring heat input for the reaction to proceed in its forward direction. Usually, an excess amount of steam is also needed to promote the conversion of the carbonaceous feedstock to carbon monoxide and hydrogen:

However, excess steam used in this reaction hurts the thermal efficiency of the process. Therefore, this reaction is typically combined with other gasification reactions in practical applications.

The hydrogen/carbon monoxide ratio of the product synthesis gas depends upon the synthesis chemistry as well as process engineering.

See also: Gasification, Gasifiers.

Steam-Methane Reforming

Steam-methane reforming is the benchmark process that has been employed over a period of several decades for hydrogen production. The process involves reforming natural gas in a continuous catalytic process in which the major reaction is the formation of carbon monoxide and hydrogen from methane and steam:

Higher-molecular-weight feedstocks can also be reformed to hydrogen:

That is,

In the actual process, the feedstock is first desulfurized by passage through activated carbon, which may be preceded by caustic and water washes. The desulfurized material is then mixed with steam and passed over a nickel-based catalyst (730 to 845°C, 1,350 to 1,550°F and 400 psi). Effluent gases are cooled by the addition of steam or condensate to approximately 370°C (700°F), at which point carbon monoxide reacts with steam in the presence of iron oxide in a shift converter to produce carbon dioxide and hydrogen:

The carbon dioxide is removed by amine washing; the hydrogen is usually a high-purity (>99%) material.

Since the presence of any carbon monoxide or carbon dioxide in the hydrogen stream can interfere with the chemistry of the catalytic application, a third stage is used to convert of these gases to methane:

For many refiners, sulfur-free natural gas (CH_4) is not always available to produce hydrogen by this process. In that case, higher-boiling hydrocarbon derivatives (such as propane, butane, or naphtha) may be used as the feedstock to generate hydrogen. The net chemical process for steam methane reforming is then given by the equation:

Indirect heating provides the required overall endothermic heat of reaction for the steam-methane reforming.

One way of overcoming the thermodynamic limitation of steam reforming is to remove either hydrogen or carbon dioxide as it is produced, hence shifting the thermodynamic equilibrium towards the product side. The concept for sorption-enhanced methane steam reforming is based on in situ removal of carbon dioxide by a sorbent such as calcium oxide (CaO).

Sorption enhancement enables lower reaction temperatures, which may reduce catalyst coking and sintering, while enabling use of less expensive reactor wall materials. In addition, heat release by the exothermic carbonation reaction supplies most of the heat required by the endothermic reforming reactions. However, energy is required to regenerate the sorbent to its oxide form by the energy-intensive calcination reaction, i.e.,

Use of a sorbent requires either that there be parallel reactors operated alternatively and out of phase in reforming and sorbent regeneration modes, or that sorbent be continuously transferred between the reformer/carbonator and regenerator/calciner.

In autothermal (or secondary) reformers, the oxidation of methane supplies the necessary energy and carried out either simultaneously or in advance of the reforming reaction. The equilibrium of the methane steam reaction and the water-gas shift reaction determines the conditions for optimum hydrogen yields. The optimum conditions for hydrogen production require high temperature at the exit of the reforming reactor (800 to 900°C; 1,470 to 1,650°F), high excess of steam (molar steam-to-carbon ratio of 2.5 to 3), and relatively low pressures (below 450 psi). Most commercial plants employ supported nickel catalysts for the process.

The steam-methane reforming process described briefly above would be an ideal hydrogen production process if it was not for the fact that large quantities of natural gas, a valuable resource, are required as both feed gas and combustion fuel. For each mole of methane reformed, more than one mole of carbon dioxide is co-produced and must be disposed. This can be a major issue as it results in the same amount of greenhouse gas emission as would be expected from direct combustion of natural gas or methane. In fact, the production of hydrogen as a clean burning fuel by way of steam reforming of methane and other fossil-based hydrocarbon fuels is not in environmental balance if in the process, carbon dioxide and carbon monoxide are generated and released into the atmosphere, although alternate scenarios are available. Moreover, as the reforming process is not totally efficient, some of the energy value of the hydrocarbon fuel is lost by conversion to hydrogen but with no tangible environmental benefit, such as a reduction in emission of greenhouse gases. Despite these apparent shortcomings, the process has the following advantages: (i) produces 4 moles of hydrogen for each mole of methane consumed, (ii) feedstocks for the process (methane and water are readily available), (iii) the process is adaptable to a wide range of hydrocarbon feedstocks, (iv) operates at low pressures, less than 450 psi, (v) requires a low steam/carbon ratio on the order of 2.5 to 3, (vi) good utilization of input energy (reaching 93%), (vii) can use catalysts that are stable and resist poisoning, and (viii) good process kinetics.

Liquid feedstocks, either liquefied petroleum gas or naphtha, can also provide backup feed, if there is a risk of natural gas curtailments. The feed handling system needs to include a surge drum, feed pump, vaporizer (usually steam-heated) followed by further heating before desulfurization. The sulfur in liquid feedstocks occurs as mercaptans, thiophene derivatives, or higher-boiling compounds. These compounds are stable and will not be removed by zinc oxide; therefore, a hydrogenation unit will be required. In addition, as with refinery gas, olefins must also be hydrogenated if they are present.

The reformer will generally use a potash-promoted catalyst to avoid coke buildup from cracking of the higher-boiling feedstock. If liquefied petroleum gas is to be used only occasionally, it is often possible to use a methane-type catalyst at a higher steam/carbon ratio to avoid coking. Naphtha will require a promoted catalyst unless a pre-former is used.

Steam-Naphtha Reforming

Steam-naphtha reforming is a continuous process for the production of hydrogen from liquid hydrocarbon derivatives and is, in fact, similar to steam-methane reforming that is one of several possible processes for the production of hydrogen from low-boiling hydrocarbon derivatives other than ethane. A variety of naphtha-types in the naphtha boiling range may be employed, including feeds containing up to 35% aromatics. Thus, following pretreatment to remove sulfur compounds, the feedstock is mixed with steam and taken to the reforming furnace (675 to 815°C, 1,250 to 1,500°F, 300 psi, 2,068 kPa), where hydrogen is produced.

Steam Reforming

Steam reforming (sometimes referred to as reforming or steam methane reforming) is another well-known method for making hydrogen. Natural gas is the most common fuel used in steam reforming.

In the steam reforming process, low-boiling hydrocarbon derivatives such as methane are reacted with steam to form hydrogen:

H is the heat of reaction. A more general form of the equation that shows the chemical balance for higher-boiling hydrocarbon derivatives is:

The reaction is typically carried out at approximately 815°C (1,500°F) over a nickel catalyst packed into the tubes of a reforming furnace. The high temperature also causes the hydrocarbon feedstock to undergo a series of cracking reactions, plus the reaction of carbon with steam:

Carbon is produced on the catalyst at the same time that hydrocarbon is reformed to hydrogen and carbon monoxide. With natural gas or similar feedstock, reforming predominates and the carbon can be removed by reaction with steam as fast as it is formed. When higher-boiling feedstocks are used, the carbon is not removed fast enough and builds up, thereby requiring catalyst regeneration or replacement. Carbon buildup on the catalyst (when high-boiling feedstocks are employed) can be avoided by the addition of alkali compounds, such as potash, to the catalyst, thereby encouraging or promoting the carbon-steam reaction.

However, even with an alkali-promoted catalyst, feedstock cracking limits the process to hydrocarbon derivatives with a boiling point less than 180°C (350°F). Natural gas, propane, butane, and low-boiling naphtha are most suitable. Pre-reforming, a process that uses an adiabatic catalyst bed operating at a lower temperature, can be used as a pretreatment to allow higher-boiling feedstocks to be used with lower potential for carbon deposition (coke formation) on the catalyst.

After reforming, the carbon monoxide in the gas is reacted with steam to form additional hydrogen (the water-gas shift reaction):

This leaves a mixture consisting primarily of hydrogen and carbon monoxide that is removed by conversion to methane:

The critical variables for steam reforming processes are (i) temperature, (ii) pressure, and (iii) the steam/hydrocarbon ratio. Steam reforming is an equilibrium reaction, and conversion of the hydrocarbon feedstock is favored by high temperature, which in turn requires higher fuel use. Because of the volume increase in the reaction, conversion is also favored by low pressure, which conflicts with the need to supply the hydrogen at high pressure. In practice, materials of construction limit temperature and pressure.

On the other hand, and in contrast to reforming, shift conversion is favored by low temperature. The gas from the reformer is reacted over iron oxide catalyst at 315 to 370°C (600 to 700°F) with the lower limit being dictated activity of the catalyst at low temperature.

Hydrogen can also be produced by partial oxidation (POX) of hydrocarbon derivatives in which the hydrocarbon is oxidized in a limited or controlled supply of oxygen:

The shift reaction also occurs, and a mixture of carbon monoxide and carbon dioxide is produced in addition to hydrogen. The catalyst tube materials do not limit the reaction temperatures in partial oxidation processes, and higher temperatures may be used that enhance the conversion of methane to hydrogen. Indeed, much of the design and operation of hydrogen plants involves protecting the reforming catalyst and the catalyst tubes because of the extreme temperatures and the sensitivity of the catalyst. In fact, minor variations in feedstock composition or operating conditions can have significant effects on the life of the catalyst or the reformer itself. This is particularly true of changes in molecular weight of the feed gas, or poor distribution of heat to the catalyst tubes.

Since the high temperature takes the place of a catalyst, partial oxidation is not limited to the lower-boiling feedstocks that are required for steam reforming. Partial oxidation processes were first considered for hydrogen production because of expected shortages of lower-boiling feedstocks and the need to have available a disposal method for higher-boiling, high-sulfur streams such as asphalt or crude oil coke.

Catalytic partial oxidation, also known as auto-thermal reforming, reacts oxygen with a low-boiling feedstock and by passing the resulting hot mixture over a reforming catalyst. The use of a catalyst allows the use of lower temperatures than in non-catalytic partial oxidation and which causes a reduction in oxygen demand.

The feedstock requirements for catalytic partial oxidation processes are similar to the feedstock requirements for steam reforming, and low-boiling hydrocarbon derivatives from refinery gas to naphtha are preferred. The oxygen substitutes for much of the steam in preventing coking and a lower steam/carbon ratio is required. In addition, because a large excess of steam is not required, catalytic partial oxidation produces more carbon monoxide and less hydrogen than steam reforming.

The steam reforming process is the most common method used to make hydrogen industrially. One benefit is that it is cheaper than producing hydrogen by electrolysis. However, a big drawback is the amount of carbon dioxide produced during the process. If the steam reforming process is to catch on as a means of mass-producing hydrogen fuel, the issue of what to do with the carbon dioxide produced must be addressed. Carbon dioxide can build up and trap heat on the planet. This condition is known as global warming. Potential solutions to the carbon dioxide issue with steam reforming exist, and all are costly. The carbon dioxide could be stored in empty gas wells or oil wells where the reservoirs of gas or oil have been depleted. Saline aquifers, which are underground pockets of saltwater, are another storage possibility. So are coal seams (where coal can be found) that are so deep underground that they cannot be mined.

Another positive aspect is that of all the fossil fuels, natural gas is the cleanest burning. In other words, it gives off fewer by-products that can contribute to pollution. The use of natural gas to make hydrogen might help in the creation of an infrastructure for the distribution of hydrogen. Since there are stations that already distribute natural gas, the natural gas could be transported there and converted to hydrogen via steam reforming on site and on a small scale. This means of production could provide hydrogen for cars that run on either hydrogen fuel cells or hydrogen-powered internal combustion engines.

Steam Regenerative Caustic Treating Process

The gas processing (gas cleaning, gas treating) industry. The hydrocarbon processing industry has historically used caustic solutions to extract or treat acidic impurities (mainly RSH) in hydrocarbon liquid streams. When quantities of

acid gas contaminants are small (typically less than 200 ppm w/w), a simple caustic wash is effective and economical. However, as the quantity of acid gas contaminants rises, once-through caustic washing processes can be expensive due to high chemical consumption and disposal costs of nonregenerable byproducts, making this approach impractical.

Several caustic processes, both regenerative and non-regenerative, can be used to remove sulfur compounds from gas streams. The method or combination of methods that can be used depends on the mercaptan characteristics and the product specification that must be met.

One of the common processes for treating hydrocarbon liquids is the use of regenerative caustic wash with sodium hydroxide (NaOH). The high pH allows the caustic to react with the weakly acidic mercaptan derivatives to form mercaptide salts followed by conversion of the mercaptides to disulfides by oxidation. These disulfides will remain in the sweetened hydrocarbon product, and the overall sulfur content of the gas stream remains unchanged. However, the sulfur leaves as odorless disulfide derivatives rather than mercaptans that are quite malodorous even at ppm levels.

The steam-regenerative caustic treating process is directed toward removal of mercaptans from such products as low-boiling, straight-run naphtha. The caustic is regenerated by steam blowing in a stripping tower. The nature and concentration of the mercaptans to be removed dictate the quantity and temperature of the process. However, the caustic solution gradually deteriorates because of the accumulation of material that cannot be removed by stripping; the caustic quality must be maintained by either continuous or intermittent discard, and replacement, of a minimum amount of the operating solution.

Non-regenerative caustic treatment processes are applicable if the concentrations of the contaminants are low. The use of a non-regenerative solid potassium hydroxide (KOH) bed is effective for removal of hydrogen sulfide but not for other sulfur compounds. However, this type of treatment process produces a waste spent caustic stream that must be further processed and disposed. Since the caustic is consumed and requires continuous makeup, there is an associated operating cost.

Steam Turbine

The steam turbine is a device that extracts thermal energy from pressurized steam and uses it to do mechanical work on a rotating output shaft. The turbine is a form of heat engine that derives much of its improvement in thermodynamic efficiency from the use of multiple stages in the expansion of the steam, which results in a closer approach to the ideal reversible expansion process. Because the turbine generates rotary motion, it is particularly suited to be used to drive an electrical generator (Figure S-3).

Figure S-3 A steam turbine generator system.

The turbine blades are of two basic types: (i) blades and (ii) nozzles (Figure S-4). Blades move entirely due to the impact of steam on them, and their profiles do not converge. This results in a steam velocity drop and essentially no pressure drop as steam moves through the blades. A turbine composed of blades alternating with fixed nozzles is referred to as an impulse turbine – other names such as Curtis turbine, Rateau turbine, and Brown-Curtis turbine are also used.

Nozzles appear similar to blades, but their profiles converge near the exit. This results in a steam pressure drop and velocity increase as steam moves through the nozzles. Nozzles move due to both the impact of steam on them and the reaction due to the high-velocity steam at the exit. A turbine composed of moving nozzles alternating with fixed nozzles is often referred to as a reaction turbine or a Parsons turbine.

Horizontal axis	Cross-flow axis	Vertical axis

Buoyant mooring		(straight blade)
		Darrieus
		(curved blade)
		Gorlov
		(helical blade)
		Savonius
		(straight/curved blade)

Figure S-4 Types of turbine blades.

Except for low-power applications, turbine blades are arranged in multiple stages (compounding) which greatly improves efficiency at low speeds. A reaction stage is a row of fixed nozzles followed by a row of moving nozzles. Multiple reaction stages divide the pressure drop between the steam inlet and exhaust into numerous small drops, resulting in a pressure-compounded turbine. Impulse stages may be pressure-compounded, velocity-compounded, or pressure-velocity compounded. A pressure-compounded impulse stage is a row of fixed nozzles followed by a row of moving blades, with multiple stages for compounding. This is also known as a Rateau turbine, after its inventor. A velocity-compounded impulse stage (also called a Curtis wheel) is a row of fixed nozzles followed by two or more rows of moving blades alternating with rows of fixed blades. This divides the velocity drop across the stage into several smaller drops. A series of velocity-compounded impulse stages is referred to as a pressure-velocity compounded turbine.

Steam turbines differ from reciprocating engines, internal combustion engines, and gas turbines in that the fuel is burned in a piece of equipment, the boiler, which is separate from the power generation equipment. The energy is transferred from the boiler to the steam turbine generator by an intermediate medium, typically steam under pressure. As mentioned previously, this separation of functions enables steam turbines to operate with an enormous variety of fuels. The topic of boiler fuels, their handling, combustion, and the clean-up of the effluents of such combustion is a separate and complex issue that is addressed in the fuels and emissions sections of this report.

For sizes up to (approximately) 40 MW, horizontal industrial boilers are built. This enables them to be shipped via rail car, with considerable cost savings and improved quality, as the cost and quality of factory labor is usually both lower in cost and greater in quality than field labor. Large shop-assembled boilers are typically capable of firing only gas or distillate oil, as there is inadequate residence time for complete combustion of most solid and residual fuels in such designs. Large, field-erected industrial boilers firing solid and residual fuels bear a resemblance to utility boilers except for the actual solid fuel injection. Large boilers usually burn pulverized coal; however, intermediate and small boilers burning coal or solid fuel employ various types of solids feeders.

Sterols

Sterol is a chemical compound with the formula $C_{17}H_{28}O$. The name is also used generically for compounds that are derived from this one by substituting other chemical groups for some of the hydrogen atoms, or modifying the bonds in the ring.

The sterols (or steroid alcohols) are a subgroup of the steroids and an important class of organic molecule which occur naturally in plants, animals, and fungi. The most familiar type of animal sterol is cholesterol which is vital to cell membrane structure, and functions as a precursor to fat-soluble vitamins and steroid hormones.

Sterols, which are based on a saturated, condensed ring structure, are widely distributed in animals and plants and are also believed to be source material for crude oil, although little is known of their natural degradation reactions. Additional classes of compounds that also make up the source material are lipids and terpenoids and, possibly, the humic substances, specifically humic acids and, to a lesser extent, fulvic acids.

Stoker Combustors

Stoker combustors improve on operation of the pile burners by providing a moving grate which permits continuous ash collection, thus eliminating the cyclic operation characteristic of traditional pile burners. In addition, the fuel is spread more evenly, normally by a pneumatic stoker, and in a thinner layer in the combustion zone, giving more efficient combustion.

Stoker-fired boilers were first introduced in the 1920s for coal, and in the late 1940s, the Detroit Stoker Company installed the first traveling grate spreader stoker boiler for wood. In the basic stoker design, the bottom of the furnace is a moving grate which is cooled by under-fire air. The under-fire air rate defines the maximum temperature of the grate and thus the allowable feed moisture content. More modern designs include the Kablitz grate, a sloping reciprocating water-cooled grate. Reciprocating grates are attractive because of simplicity and low fly ash carry-over. Combustion is completed by the use of overfire air. The furnace wall configurations include straight and bull nose water walls.

See also: Combustion.

Straight Vegetable Oil

In common use, the term vegetable oil may refer exclusively to vegetable fats which are liquid at room temperature. Also, straight-run vegetable oil is vegetable oil that has been distilled and not used for any other purpose. Once used for, say cooking, the vegetable oil may be referred to as used cooking oil or waste cooking oil and is not suitable for use as a vehicle fuel because of the potential contaminant that could interfere with the smooth running of the engine.

Vegetable oils are usually edible; non-edible oils derived mainly from petroleum are termed mineral oils. Vegetable oil is extracted from seeds, or less often, from other parts of fruits and are mixtures of triglyceride derivatives. Soybean

oil, grape seed oil, and cocoa butter are examples of fats from seeds. Olive oil and palm oil are examples of oils. Straight-run vegetable oil is any vegetable oil that has not been optimized through the process of transesterification.

Vegetable oil can power a diesel-engine vehicle, but the effects on the environment are still unclear and debatable. Often referred to as veggie cars or grease cars, these vehicles have fuel systems modified to burn both diesel fuel and straight vegetable oil.

Stratosphere

The stratosphere forms the middle layer of the homosphere and lies directly above the troposphere in which the temperature rises to a maximum of ca. -2°C (28°F) with increasing altitude. This phenomenon is due to the presence of ozone (O_3) which may reach a level of around 10 ppm v/v in the mid-range of the stratosphere. The heating effect is caused by the absorption of ultraviolet radiation energy by ozone. The situation can become even more complicated due to the formation of additional ozone in the gaseous plumes from urban centers.

The stratosphere has a thickness in excess of 25 miles thick and contains the infamous ozone layer. Temperature increases upward in the stratosphere as ozone molecules concentrated in the upper two-thirds of the layer absorb ultraviolet solar radiation, and decreasing air density results in greater agitation (more kinetic energy) of atoms. Maximum temperatures approach 0°C (32°F) at the stratopause that separates the stratosphere and the overlying mesosphere. The warm cap of the stratosphere overlying the relatively cool troposphere results in a stable atmospheric configuration as the cool air cannot rise into the warm layer.

Straw

Straw (residual herbaceous biomass) is the main residual herbaceous material for energy application nowadays.

As it is a residual product, its availability for energy purposes is driven by the cereals markets and does not have autonomous market behavior. In addition, farms consume significant quantities of straw internally – as bed material for livestock, grain drying, etc. Some straw is also chaffed and returned back to the field as soil ameliorator. The net straw yield per hectare for energy application also depends on the crop, the grain yield per hectare, climate and cultivation conditions, etc. Nevertheless, one can roughly estimate that the average straw yield per hectare is approximately 50 to 65% of the grain yield per hectare from cereals and oilseeds.

Similar to herbaceous crops, straw usually has lower moisture content than woody biomass. Conversely, it has a lower calorific value, bulk density, ash melting point and higher content of ash, and problematic inorganic component such as chlorine, potassium, and sulfur, which cause corrosion and pollution. The last two drawbacks can be relatively easily overcome by leaving straw on the field for a while. In such a way, rainfall “washes” it naturally from a large part of potassium and chlorine. Alternatively, fresh straw can be directly shipped to the gasification plant, where it is washed by dedicated facilities at moderate temperatures (50 to 60°C ; 120 to 140°F). Due to washing, the initially low moisture content of straw becomes higher in both cases, and hence, a mandatory drying is applied afterwards. In both cases also, the content of corrosive components is reduced, but not completely taken out.

In order to decrease handling costs, straw and dedicated herbaceous energy crops are usually baled before being shipped to the gasification plant. The weight and the size of bales depend on the baling equipment and on the requirements of the gasification plant.

Stretford Process

The Stretford process is one of the oldest commercial liquid redox processes, and it is based on a vanadium and anthraquinone redox system. The process was developed to remove hydrogen sulfide (H_2S) from town gas and was the first liquid phase, oxidation process for converting hydrogen sulfide into sulfur to gain widespread commercial

acceptance. The process is a wet oxidation process and employs a solution containing vanadium salts and anthraquinone disulfonic acid. Most hydrogen sulfide removal processes return the hydrogen sulfide unchanged, but if the quantity involved does not justify installation of a sulfur recovery plant (usually a Claus plant), it is necessary to select a process that directly produces elemental sulfur.

The Stretford Process removes hydrogen sulfide by continuous liquid washing using an adequate alkaline solution containing dyestuff intermediates. The hydrogen sulfide is converted to elemental sulfur, which is separated from the solution, washed to remove the solution from the sulfur cake, and stored ready for disposal. The process was the first liquid phase, oxidation process for converting hydrogen sulfide into sulfur to gain widespread commercial acceptance. The process uses reduction-oxidation (redox) chemistry to oxidize the hydrogen sulfide into elemental sulfur, in an alkaline solution containing vanadium as an oxygen carrier.

See also: Gas Cleaning, Gas Processing, Gas Treating, Redox Processes.

Stripping

Stripping is a physical separation process in which one or more components are removed from a liquid stream by a vapor stream. In industrial applications, the liquid and vapor streams can have co-current or countercurrent flows. Stripping is usually carried out in either a packed or trayed column and works on the basis of mass transfer in which the component in the liquid phase is transferred to the vapor phase. Stripping is mainly conducted in trayed towers (plate columns) and packed columns, and less often in bubble columns, spray towers, and centrifugal contactors.

Trayed towers consist of a vertical column with liquid flowing in the top and out the bottom. The vapor phase enters in the bottom of the column and exits out of the top. Inside of the column are trays or plates. These trays force the liquid to flow back and forth horizontally, while the vapor bubbles up through holes in the trays. The purpose of these trays is to increase the amount of contact area between the liquid and vapor phases.

Packed columns are similar to trayed columns in that the liquid and vapor flows enter and exit in the same manner. The difference is that in packed towers, there are no trays. Instead, packing is used to increase the contact area between the liquid and vapor phases. There are many different types of packing used, and each one has advantages and disadvantages.

Frequently, air, steam, and inert gases (including hydrocarbon gases) and is based on solubility, stability, corrosivity, and availability. As stripping agents are gases, operation at nearly the highest temperature and lowest pressure that will maintain the components and not vaporize the liquid feed stream is desired. This allows for the minimization of flow. As with all other variables, minimizing cost while achieving efficient separation is the ultimate goal.

The size of the equipment, and particularly the height and diameter, is important in determining the possibility of flow channeling that would reduce the contact area between the liquid and vapor streams. If flow channeling is suspected to be occurring, a redistribution plate is often necessary to, as the name indicates, redistribute the liquid flow evenly to reestablish a higher contact area.

Packed columns, and particularly when random packing is used, are usually favored for smaller columns with a diameter less than 2 feet and a packed height of not more than 20 feet. Packed columns can also be advantageous for corrosive fluids, high foaming fluids, when fluid velocity is high, and when particularly low pressure drop is desired. Trayed strippers are advantageous because of ease of design and scale up. Structured packing can be used similar to trays despite possibly being the same material as dumped (random) packing. Using structured packing is a common method to increase the capacity for separation or to replace damaged trays.

Trayed strippers can have sieve, valve, or bubble cap trays, while packed strippers can have either structured packing or random packing. Trays and packing are used to increase the contact area over which mass transfer can occur as mass transfer theory dictates. Packing can have varying material, surface area, flow area, and associated pressure drop. Older generation packing includes ceramic Raschig rings and Berl saddles. More common packing materials are metal and plastic Pall rings, metal and plastic Bialecki rings, and ceramic Intralox saddles. Each packing material of this newer generation improves the surface area, the flow area, and/or the associated pressure drop across the packing. Also important is the ability of the packing material to not stack on top of itself. If such stacking occurs, it drastically reduces the surface area of the material. Lattice design work has been increasing of late that will further improve these characteristics.

During operation, monitoring the pressure drop across the column can help to determine the performance of the stripper. A changed pressure drop over a significant range of time can be an indication that the packing may need to be replaced or cleaned.

Sublimation

The term *sublimation* refers to a *physical* change of state and is not used to describe the transformation of a solid to a gas in a chemical reaction. In the process, a substance undergoes a transition directly from the solid phase to the gas phase without passing through the intermediate liquid phase (Table 7.4). For example, the dissociation on heating of solid ammonium chloride (NH_4Cl) into ammonia (NH_3) and hydrogen chloride (HCl) is *not* sublimation but a chemical reaction:

Sublimation requires additional energy and is an endothermic change, and the enthalpy of sublimation (also referred to as the *heat of sublimation*) can be calculated by adding the enthalpy of fusion and the enthalpy of vaporization. The reverse process of sublimation is the process of *deposition* in which some chemicals pass directly from the gas phase to the solid phase, again without passing through the intermediate liquid phase.

Sublimation:

Solid $\rightarrow$ gas

Deposition

Gas $\rightarrow$ solid

Sugar Beets

Sugar beets and fodder beets were found to be not adapted for growth in the Southeast. While early growth was satisfactory, foliage diseases caused severe defoliation in late July and August. Regrowth of leaves was made at the expense of stored sugars; thus, yield and sugar concentrations in the roots at harvest were only approximately half of what is observed in the major beet growing areas.

Sugar beet (*Beta vulgaris*, family-Chenopodiaceae) is yet another plant which contains a high percentage of sugars stored in fleshy storage roots. It is also an important source for production of sugar as well as ethanol.

Raising crops like sugarcane, sugar beet, tapioca, potato, maize, etc., purely for production of ethanol is described as energy cropping, and the crops are called energy crops. Cultivation of plants (trees) for obtaining fuel/fire wood is described as energy plantation.

Other plants, such as Euphorbiaceae plants like *Euphorbia lathyris*, milkweed (*Asclepia speciosa*) and the tree legume *Copaifera multijuga*, produce hydrocarbon derivatives which can be converted into and used as diesel, called biodiesel. In addition, some freshwater and marine algae are also known to accumulate hydrocarbon derivatives. Some algae like Chlamydomonas and anaerobic bacteria like Clostridium produce hydrogen gas, which can be used as a pollution-free fuel. Long-term research efforts are needed to develop these organisms as sources of bioenergy.

The euphorbeans and milkweeds can be grown in relatively dry environments on lands not suited for crop production; this makes them highly attractive sources of biofuels. The Euphorbias are relatives of plants used to produce rubber; they produce a latex, which has approximately 30% hydrocarbon derivatives emulsified in water.

However, hydrocarbon derivatives, as such, are not usually produced from crops, there being insufficient amount of the hydrocarbon derivatives present in the plant tissue to make the process economical. However, biodiesel is produced from crops, thereby offering an excellent renewable fuel for diesel engines.

Sugar Cane

Sugarcane (sugar cane, *Saccharum officinarum* - family Gramineae) is the main source of raw material for sugar industry. The wastes from sugar industry include bagasse, molasses, and press mud. After extracting the cane juice for sugar production, the cellulosic fibrous residue that remains is called bagasse. It is used as the raw material (biomass) and processed variously for the production of fuel, alcohols, single cell protein as well as in paper mills. Molasses is an important by-product of sugar mills and contains 50-55% fermentable sugars. One ton of molasses can produce approximately 280 liters of ethanol. Molasses is used for the production of animal feed, liquid fuel, and alcoholic beverages.

Sugarcane residues, particularly sugarcane bagasse (SB) and leaves (SL), have been explored for both biotechnological and non-biotechnological applications. For the last three decades, sugarcane bagasse and leaves have been explored for use in lignocellulosic bioconversion, which offers opportunities for the economic utilization of residual substrates in the production of bioethanol and value-added commercial products such as xylitol, specialty enzymes, organic acids, and single-cell protein. In addition, sugarcane was the basis for the first renewable biofuel program in Brazil. Corn is the basis for the present renewable ethanol fuel industry in the United States.

Also, sugar beet, corn, and sweet sorghum are agricultural crops presently grown commercially for both carbohydrate production and animal feeds. Sugarcane, corn, and sweet sorghum are efficient at trapping solar energy and use specific biochemical pathways to recycle and trap carbon dioxide that is lost through photorespiration. Sugar beets are efficient because they store their carbohydrate in the ground.

The sugars produced by these crops are easily fermented by *Saccharomyces cerevisiae*. The sucrose produced by sugarcane, sugar beet, and sweet sorghum can be fermented directly after squeezing them from the crop. Corn traps its carbohydrate largely in the form of starch which must first be converted into glucose through saccharification with glucoamylase. The residues left over after removing fermentable sugars can also be utilized. In some cases, they end up as animal feeds, but many agricultural residues can be converted into additional fermentable sugars through saccharification with cellulase and hemicellulase. The hemicellulose sugars are not fermentable by *S. cerevisiae*, and must be converted to ethanol by pentose fermenting yeasts or genetically engineered organisms.

See also: Sugar Crops, Starch, Sugars.

Sugar Crops

Interest in ethanol production from agricultural crops has prompted research on the development of sugar crops that have not been cultivated on a widespread commercial basis in this country. Three of the principal crops now under investigation are sweet sorghum, Jerusalem artichokes, and fodder beets.

Preparation is basically a crushing and extraction of the sugars which the yeast can immediately use. But sugar crops must be dealt with fairly quickly before their high sugar and water content. The characteristics of sugar crops are variable (Table S-3), but, in general, because of the danger of such spoilage, the storage of sugar crops is not always practical.

Table S-3 Characteristics of sugar crops.

Crop	Description
Sugar Cane	High yields per acre of both sugar and crop residue are strong points of sugar cane production. The crop residue, called bagasse, is used in Brazil to provide heat for the distilleries.
Sugar beet	Although sugar beets are grown in many areas of the U.S., they must be rotated with non-root crops (1 beet crop per 4-year period is the general rule). While beet by-products cannot provide fuel for the distillery, the beet pulp and tops are excellent feed in wet or dry form. Or the tops may be left on the field for fertilizer and erosion control.
Sweet Sorghum	Sweet sorghum is a name given to varieties of a species of sorghum: <i>Sorghum bicolor</i> . This crop has been cultivated on a small scale in the past for production of table syrup, but other varieties can be grown for production of sugar. The most common types of sorghum species are those used for production of grain.
Jerusalem Artichoke	The Jerusalem artichoke has shown excellent potential as an alternative sugar crop. A member of the sunflower family, this crop is native to North America and well-adapted to northern climates. Like the sugar beet, the Jerusalem artichoke produces sugar in the top growth and stores it in the roots and tuber. It can grow in a variety of soils, and it is not demanding of soil fertility. The Jerusalem artichoke is a perennial; small tubers left in the field will produce the next crop for the next season, so no plowing or seeding is necessary.
Fodder Beets	Another promising sugar crop which presently is being developed in New Zealand is the fodder beet. The fodder beet is a high-yielding forage crop obtained by crossing two other beet species, sugar beets and mangolds. It is similar in most agronomic respects to sugar beets. The attraction of this crop lies in its higher yield of fermentable sugars per acre relative to sugar beets and its comparatively high resistance to loss of fermentable sugars during storage.
Fruit Crops	Fruit crops (e.g., grapes, apricots, peaches, and pears) are another type of feedstock in the sugar crop category. Typically, fruit crops such as grapes are used as the feedstock in wine production. These crops are not likely to be used as feedstocks for production of fuel-grade ethanol because of their high market value for direct human consumption. However, the co-products of processing fruit crops are likely to be used as feedstocks because fermentation is an economical method for reducing the potential environmental impact of untreated wastes containing fermentable sugars.

See also: Starch Crops.

Sugars and Starch

Biomass is typically composed of 75 to 90% by weight sugar species, the other 10 to 25 wt% being mainly lignin. Plants capture solar energy as fixed carbon during which carbon dioxide is converted to water and sugars $(\text{CH}_2\text{O})_x$:

The sugars produced are stored in three types of polymeric macromolecules: (i) starch, (ii) cellulose, and (iii) hemicellulose. Monosaccharides (the simple sugars) are colorless, water-soluble crystalline solids with a characteristic three-dimensional structure (Figure S-5).

Figure S-5 Representations of the naturally occurring form of glucose.

Because of the presence of numerous chiral centers (place in the molecule in which one atom is bonded to four different chemical species), various isomeric forms of the different monosaccharides exist. However, since biofuels are necessarily obtained from natural sources, the forms which are abundant in nature predominate.

In general, sugar polymers such as cellulose and starch (Figure S-6) can be readily broken down to their constituent monomers by hydrolysis, preparatory to conversion to ethanol or other chemicals. In contrast, lignin is a complex structure containing aromatic groups and is less readily degraded.

Figure S-6 Representation of the starch molecule.

Although lignocellulose is one of the cheapest and most abundant forms of biomass, it is difficult to convert this relatively unreactive material into sugars. Among other factors, the walls of lignocellulose are composed of lignin, which must be broken down in order to render the cellulose and hemicellulose accessible to acid hydrolysis. For this reason, many programs focused on ethanol production from biomass are based almost entirely on the fermentation of sugars derived from the starch in corn grain, which has increased in production over the past century (Figure 4).

Glucose (dextrose), fructose (laevulose), galactose, xylose, and ribose are common. Glucose is a simple sugar that can be readily fermented into biofuel if it can be accessed; the equation for its combustion is given here:

A large amount of heat energy is evolved in the complete combustion of one mole of pure glucose, and this exothermic reaction is the main source of metabolic energy (ATP) in cells. Glucose and other simple sugars are normally fermented into alcohols for direct use as a fuel. Starch, otherwise known as amyllum, is the polysaccharide present in all green plants and is the form by which food is stored. Glucose monomers are joined by β 1-4 glycosidic bonds in the linear helical portions of the polymer (amylose) and by β 1-5 glycosidic bonds in the branched portions (amylopectin). Plant sugars or starches of biofuel crops such as sugar cane and maize are fermented to produce ethanol.

The most widely used form of sugar for ethanol fermentation is the blackstrap molasses which contains approximately 30 to 40% w/w sucrose, 15 to 20% w/w invert sugars such as glucose and fructose, and 28 to 35% w/w of non-sugar solids.

The direct fermentation of sugarcane juice, sugar beet juice, beet molasses, fresh and dried fruits, sorghum, whey, and skim milk has been considered, but none of these could compete economically with molasses. From the viewpoint of industrial ethanol production, sucrose-based substances such as sugarcane and sugar beet juices present

many advantages including their relative abundance and renewable nature. Molasses, the non-crystallizable residue that remains after the sucrose purification, has additional advantages; it is relatively inexpensive raw material, readily available, and already used for industrial ethanol production.

Sulfa-Check Process

The Sulfa-Check process selectively removes hydrogen sulfide and mercaptans from natural gas in the presence of carbon dioxide. The process uses sodium nitrite (NaNO_2).

Gas streams with elevated oxygen levels with the Sulfa-Check process will produce some nitrogen oxides in the gas stream. Removal of hydrogen sulfide is not affected under short contact times, as the reaction is almost instantaneous. Sodium hydroxide and sodium nitrite are consumables in the processes and cannot be regenerated.

This process is accomplished in a one-step single vessel design using an aqueous solution of sodium nitrite buffered to stabilize the pH above 8. Also, there is enough strong base to raise the pH of the fresh material to 12.5. The claimed reaction with hydrogen sulfide forms elemental sulfur, ammonia, and caustic soda as follows:

Other reactions forming the oxides of nitrogen do occur, and carbon dioxide in the gas reacts with the sodium hydroxide to form sodium carbonate and sodium bicarbonate. The spent solution is a slurry of fine sulfur particles in a solution of sodium and ammonium salts.

Gas streams with elevated oxygen levels will produce some nitrogen oxides in the gas stream, and carbon dioxide in the gas reacts with sodium hydroxide to form sodium carbonate and sodium bicarbonate. Removal of hydrogen sulfide is not affected under short contact times since the reaction is almost instantaneous. Sodium hydroxide and sodium nitrite are consumables in the processes and cannot be regenerated.

SulfaClean HC Liquid Sweetening Process

The SulfaClean Process uses SulfaClean HC, a granular material that is used to remove aggregative sulfur compounds, primarily hydrogen sulfide (H_2S), in a variety of clear liquid streams.

Propane/propylene, butane, liquefied natural gas, natural gas liquids, naphtha, and other low-molecular-weight liquid hydrocarbon streams treatment reduces corrosion to pass copper strip testing and meet hydrogen sulfide limits. Dry or water saturated liquid hydrocarbon derivatives can be treated, as well as water or brines for removal of dissolved hydrogen sulfide prior to disposal.

In the process, liquids flow upward through the SulfaClean HC media. Flow rates and the system design depend on fluid type and contaminants' quantity. Systems range from single vessels or multiple parallel flow to lead/lag style applications.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Sulfatreat Process

The SulfaTreat process is a batch-type process for the selective removal of hydrogen sulfide and mercaptans from natural gas; the process is dry, using no free liquids, and can be used for all natural gas applications where a batch process is suitable.

The SulfaTreat process is a batch-type process for the selective removal of hydrogen sulfide and mercaptans from natural gas. The process is dry, using no free liquids, and can be used for all natural gas applications where a batch

process is suitable. The SulfaTreat system is a more recent development using iron oxide on a porous solid material. Unlike the iron sponge process, the SulfaTreat material is non-pyrophoric and has a higher capacity than iron sponge on a volumetric or mass basis.

In the process, the inlet gas stream enters the unit through a small inlet separator to separate out any entrained liquid, salt water, and any liquid hydrocarbon in the gas stream. The sour feed gas then passes to the top of the contactor where the SulfaTreat product (a dry, granular, free-flowing material of uniform porosity and permeability) only reacts with sulfur-containing compounds. This eliminates any side reactions with carbon dioxide that could reduce its efficiency. As the SulfaTreat bed dries out, the rate of reaction decreases. Optimum efficiency may require measuring the water content of the gas and injecting a sufficient amount of water into the influent gas to maintain a water-saturated gas and evidence of free water in the outlet gas.

The chemical cost for this processes is higher than that for iron sponge process, but this is partially offset by the ease and lower cost with which the contact tower can be cleaned out and recharged. Also, because liquids freeze and foam, antifreeze must be added in winter, and an anti-foaming agent should be available. Finally, obtaining approval to dispose of the spent chemicals, even if they are non-hazardous, is time-consuming. Two different slurry processes are described here in great detail.

See also: Gas Cleaning, Gas Processing, Gas Treating.

SulFerox Process

The SulFerox process is an iron redox process in which the hydrogen sulfide is directly oxidized to elemental sulfur while the ferric ions are reduced. These are subsequently regenerated by oxidation with air. Sulfur may be recovered as a moist filter cake or as pure liquid sulfur.

The process is mainly used for the treatment of hydrogen sulfide-containing gases such as natural gas, amine unit regenerator offgas, geothermal gas streams, and enhanced oil recovery (EOR) carbon dioxide stream.

The SulFerox process is particularly attractive for natural gas treatment when low hydrogen sulfide content and high carbon dioxide content would normally make conventional amine-based units uneconomic. The small equipment size makes the process attractive for offshore applications.

SulFerox has the following advantages over absorption-based treating processes (i) selective hydrogen sulfide removal as essentially no carbon dioxide is removed, (ii) low hydrogen sulfide content can be achieved in the treated gas (less than 5 ppm v/v), (iii) wide turndown in gas flow and/or inlet hydrogen sulfide concentration, and (iv) can operate at ambient temperature giving easy start up and shutdown.

Sulfinol Process

The Sulfinol process is a combination process that uses a mixture of amines and a physical solvent (an aqueous amine and sulfolane). The solvent consists of an aqueous amine and sulfolane.

Sulfinol has a good affinity for most of the acid gases and has the ability to release these gases in the regenerator upon pressure reduction and heat application. When operating under suitable conditions, it is capable of removing twice as much acid gas as a 20% monoethanolamine (MEA) solution. This results in a considerable reduction in plant equipment size and capital cost.

This process is, in many respects, identical to the familiar amine method and its equipment components similar to those found in amine units. The main difference is that while the conventional amine process employs a fairly diluted concentration of amine in water, removing the acid gas by chemical reaction, the Sulfinol system uses a mixture of highly concentrated amine and a physical solvent removing the acid gases by physical and chemical reactions. The concentrations of the amine and the physical solvent vary with the type of feed gas in each application. Common Sulfinol mixtures are in the range of 40% amine (also called DIPA), 40% sulfolane (an organic solvent), and 20% water.

Sulfinol has a good affinity for most of the acid gases and has the ability to release these gases in the regenerator upon pressure reduction and heat application. When operating under suitable conditions, it is capable of removing twice as much acid gas as a 20% monoethanolamine solution. A Sulfinol system consists of a gas sweetening train and rich solution regeneration equipment similar to the familiar amine units.

The feed gas passes through the scrubbers after leaving the inlet separator, to remove any traces of hydrocarbon liquids and then enters the lower section of the Sulfinol absorber at a temperature of approximately 43°C (109°F). In this vessel, the ascending gas is contacted countercurrently with a stream of lean solvent fed at a point near the top. Sweetened gas leaves the contactor overhead, and after passing through a mist extractor to recover any entrained solvent, it flows to the dehydration section for further processing.

The rich solvent, withdrawn from the bottom of the contactor, is directed next to the solvent flash tank where its hydrocarbon content is flashed off at a pressure of approximately 550 kPa. The flashed vapor goes to the fuel gas contactor and after treatment with a side stream of lean solvent is used as plant fuel. The rich solvent, free of hydrocarbon derivatives, passes through a solvent to solvent heat exchanger and then to the regenerator or Sulfinol stripper to release its acid gas content.

The rich Sulfinol is contacted in the regenerator with steam vapor generated in the reboiler, and its temperature is raised to approximately 125 to 132°C (257 to 270°F). At this temperature, the Sulfinol yields its acid load which leaves the still from overhead and passes on to the reflux condenser and then to the accumulator. The hot lean solvent is cooled and pumped to the surge tank. A small side stream is directed through the filters to remove such impurities as iron oxide and various solids. The lean solvent from the surge tank is pumped again to the top of the contactor, where it repeats the cycle.

Meanwhile, the cooled acid gases from the reflux accumulator may be subjected to further treatment to remove their hydrocarbon content before they are fed to the sulfur plant. The condensed water vapor is also pumped back into the still as reflux.

Sulfinol systems are simple in operation and are considered more economical to run. Smaller size equipment can be employed in this system, resulting in fewer operational problems and lower maintenance. However, the following considerations concerning their performance and best efficiency are worthy of mention.

The correct proportion of the water content in the circulating solvent is regarded as extremely important. Since water vapor is continuously lost with the acid gas from the reflux accumulator, it must be replaced almost simultaneously, and at the same rate, in order to avoid the disintegration of the design solution mixture. Sulfinol solution of low water content will require increased power to pump and will possibly upset the operations in the contactor and stripper towers. On the other hand, a solution mixture of too high water content will not adequately absorb the acid gases from the feed stream, particularly during peak load periods.

To determine the proper water content in the mixture, Sulfinol solution tests are taken during each shift or as required. Water makeup needed is usually injected into the base of the stripper in the form of live low pressure steam. This steam is manually controlled, and with the help of a flow indicator, the correct amount of water can be added to balance the mixture. Large quantities of water, which may be needed quickly in the system, are taken care of by opening the emergency line provided for this purpose in the suction side of the reflux pump.

Another operating consideration is the degree of conditioning the solvent receives in the stripping section. Recommended H₂S content in the returning lean solvent should not be higher than 0.5 to 0.8 ppm of solvent; this can be achieved by maintaining the correct stripping pressures and temperatures in the still. Some regenerator columns may be operated under vacuum, which is considered an aid in reclaiming the Sulfinol solution and removing the high boiling degradation products. Clean filters and injection of proper amounts of chemicals into the solution is another means of maintaining cleanliness and purity of Sulfinol mixtures.

The solvent flow rates should be also constantly observed and held fairly constant in order to avoid producing residue gas off specifications. Flow rates should only be altered when the feed gas rates change, and this alteration should be done in a gentle manner. Some plants are equipped with automatic shut-down devices to shut down the feed gas in the event of low solvent flows. Restarting of these devices is done manually, and personnel should be thoroughly familiar with their operation.

Normally, foaming is not considered a serious problem in Sulfinol systems. Slugs of high-boiling liquid hydrocarbon derivatives may enter the contactor without causing the tower to foam. Pressure differential recorders, however, may be installed across the contactor and an alarm installed to warn personnel of the forthcoming conditions.

Sulfinol has shown many advantages as a gas sweetening process and has found application in a wide range of feed gases. It is an ideal method to treat acid gases containing hydrogen sulfide in excess of 5% v/v and has no difficulty in meeting the strictest pipeline specifications.

The acid gas loading capacity of Sulfinol is twice as much as MEA; consequently, the solution circulating rates are half of that required in other processes. This results in the employment of smaller size equipment and lower volumes of utility requirements. Sulfinol appears to be a stable solvent and is a mixture affected least by undesirable side reactions, considered as major problems in ethanolamine systems. It has a remarkable resistance to degradation, particularly in the presence of carbonyl sulfide and mercaptans. Sour streams, however, high in carbon dioxide and carbon disulfide, may require the use of a simple reclaiming unit.

Maintenance problems in Sulfinol processes are low, since fouling of equipment surfaces such as heat exchangers, contactor, or stripper trays and pump internals is rare. In fact, the solvent will dissolve the soft scale and sludge formations accumulated there or carried over from other stages. The life of equipment is generally longer in these systems, particularly when the normal operating conditions are constantly observed and maintained.

Some drawbacks, however, are also present in Sulfinol systems, and hydrocarbon contamination is considered as the most serious one. Sulfinol absorbs a large part of the higher-boiling hydrocarbon derivatives present in the feed stream and releases it in the still upon regeneration, only to find its way into the sulphur plant, unless it is removed in time. Hydrocarbon presence in the acid gas lowers the quality of sulfur and puts an added load to the air blowers. To prevent the hydrocarbon derivatives entrance into the sulfur plant, activated charcoal beds are usually installed in the feed line.

In sour parts of the process, where the temperature is a little higher, the corrosion rates may be more severe than elsewhere. Carbon steel or stainless steel materials are effectively employed in these areas to cope with the corrosion problem.

The Sulfinol-D process uses diisopropanolamine (DIPA), while Sulfinol-M uses methyl diethanolamine (MDEA). The mixed solvents allow for better solvent loadings at high acid gas partial pressures and higher solubility of carbonyl sulfide and organic sulfur compounds than straight aqueous amines.

The Sulfinol-D process is primarily used in cases where selective removal of hydrogen sulfide is not of primary concern, but where partial removal of organic sulfur compounds (mercaptans, RSH, and carbon disulfide) is desired, typically in natural gas and refinery applications. The Sulfinol-D configuration is also able to remove some carbonyl sulfide via physical solubility in sulfolane and partial hydrolysis to hydrogen sulfide induced by the diisopropanolamine (DIPA). However, complete removal of carbonyl sulfide by Sulfinol-D cannot be guaranteed. Unlike solvents that use other primary and secondary amines (monoethanolamine, MEA, diethanolamine, DEA) Sulfinol-D is claimed not to be degraded by these sulfur compounds.

Sulfinol-M is used when a higher degree of hydrogen sulfide selectivity is needed. Hydrogen sulfide selectivity in Sulfinol-M is controlled by the relative reaction rate of the reaction of hydrogen sulfide with methyl diethanolamine as well as by the physical solubility of hydrogen sulfide and carbon dioxide in the solvent.

The Sulfinol-X process is a regenerable amine process for acid-gas removal that uses a mixture of two or more alkanolamines – typically a base amine such as MDEA or di-isopropanolamine (Sulfinol-X) and an accelerator. The capacity for removal of carbonyl sulfide, mercaptans, and organic sulfides from gas streams is excellent because of the improved solubility of these compounds in the solvent – a mixture of water, sulfolane, and one or more alkanolamines.

The Sulfinol-X process can achieve a higher carbon dioxide loading capacity. It facilitates the design of smaller absorber columns with fewer trays.

Sulfur-Containing Gas Removal

Historically, the first method for removing sulfur dioxide from flue gases consisted of simple water scrubbing of the flue gas to absorb sulfur dioxide into solution, and the method was first used in London in during the 1930s. Since then, various regulatory organizations in many countries have set standards for sulfur dioxide emissions which must be met.

Sulfur dioxide represents a high percentage of the sulfur oxide pollutants generated in combustion. The removal of the sulfur dioxide from the combustion gases before they are released to the stack is essential, and a considerable number of procedures exist for flue gas desulfurization (FGD). These procedures may be classified as wet or dry depending on whether a water mixture is used to absorb the sulfur dioxide or whether the acceptor is dry.

There are a variety of processes which are designed for sulfur dioxide removal from stack gas, but scrubbing process utilizing limestone (CaCO_3) or lime [$\text{Ca}(\text{OH})_2$] slurries have found regular use for stack gas scrubbing. Use of dry limestone or dolomite (CaCO_3 , MgCO_3) within the combustor is an in situ method for sulfur dioxide removal, thereby eliminating the wet sludge from wet processes. The dry carbonate mineral is injected with the coal followed by recovery of the calcined product along with sulfite and sulfate salts:

The majority of the stack gas scrubbing processes is designed to remove sulfur dioxide from the gas streams; some processes are also able to remove nitrogen oxide(s).

In addition to limestone added to the coal, the production of sulfur oxides can also be mitigated can also be removed by modifications of the combustion chamber as well as flame temperature regulation and techniques that lower combustion temperatures, such as injection of steam into the combustion which will also reduce emissions of nitrogen oxide(s).

The procedures for the removal of sulfur dioxide can be classified further as *regenerative* or *non-regenerative*, depending upon whether the chemical used to remove the sulfur dioxide can be regenerated and used again or whether the chemical is unusable and passes to disposal.

In the *wet regenerative processes*, either elemental sulfur or sulfuric acid is recovered. In the wet non-regenerative processes, using lime and/or limestone, calcium sulfite or calcium sulfate sludge is produced that is disposed. Wet scrubbing processes contact the flue gas with a solution or slurry for sulfur dioxide removal.

In a wet limestone process, the flue gas contacts a limestone slurry in a scrubber:

Both the sulfite and the sulfate absorb water of hydration to form the sulfite/sulfate sludge.

In a wet lime process, a gas stream containing the sulfur dioxide is reacted with a wet lime slurry to form the sulfite:

There is subsequent conversion, by oxidation, to the sulfate.

In the double alkali non-regenerative procedure, flue gas is scrubbed with a soluble alkali such as sodium sulfite which is subsequently regenerated with lime to form insoluble calcium sulfite:

After this, disposal of the calcium sulfite slurry occurs, and the spent absorbent, sodium bisulfite, is regenerated by thermal means:

In all of these procedures, water exits the system as vapor in the flue gas.

In either the lime/limestone or sodium sulfite/lime scrubbing processes, the hydrated calcium sulfite and calcium sulfate can be of some environmental concern when the issue of disposal arises. This has, more than anything else, promoted efforts to develop alternate dry scrubbing procedures for the removal of sulfur dioxide. The dry systems have the additional advantage of reducing the pumping requirements necessary for the wet systems.

The tendency is to advocate the use of dry lime scrubbing systems, thereby producing a waste stream that can be handled by conventional fly ash removal procedures. There are also dry processes, such as the metal oxide processes, in which sulfur dioxide can be removed from gas streams by reaction with a metal oxide. These processes, which are able to operate at high temperatures (approximately 400°C; 750°F), are suitable for hot gas desulfurization without a cooling step. The metal oxides can usually be regenerated by aerial oxidation, to convert any metal sulfide(s) back to the oxide(s) or by use of a mixture of hydrogen and steam.

Membranes have found increasing industrial use in the past four decades and have also been suggested as being appropriate for the separation of hydrogen sulfide and sulfur dioxide as well as being applicable to higher temperature conditions.

The removal of carbonyl sulfide from gas streams, especially those that are destined for the manufacture of synthesis gas, is possible using:

See also: Gas Cleaning, Gas Processing, Gas Treating.

Sulfur Cycle

The sulfur cycle is the collection of processes by which sulfur moves between rocks, waterways, and living systems. The global sulfur cycle depends on the activities of metabolically and phylogenetically diverse microorganisms, most of which reside in the ocean. This involves the transformations of sulfur species through different oxidation states, which play an important role in both geological and biological processes. Steps of the sulfur cycle are: (i) mineralization of organic sulfur into inorganic forms, such as hydrogen sulfide (H_2S), elemental sulfur, as well as sulfide minerals, (ii) oxidation of hydrogen sulfide, sulfide, and elemental sulfur (S) to sulfate (SO_4^{2-}), (iii) reduction of sulfate to sulfide, and (iv) incorporation of sulfide into organic compounds (including metal-containing derivatives).

The ocean represents a major reservoir of sulfur on Earth, with large quantities in the form of dissolved sulfate and sedimentary minerals (e.g., gypsum and pyrite). Sulfur occurs in a variety of valence states, ranging from -2 (as in sulfide and reduced organic sulfur) to +6 (as in sulfate). Sulfate is the most stable form of sulfur on today's oxic Earth; weathering and leaching of rocks and sediments are its main sources to the ocean. In addition, the reduced inorganic forms of sulfur, with oxidation states of -2 and 0 (as in elemental sulfur) are quite common in anoxic environments, with sulfur compounds of mixed valence states (e.g., thiosulfate and polythionates) produced transiently. The natural release of volatile organic sulfur compounds from the ocean, mainly as dimethyl sulfide (DMS, CH_3SCH_3), transports sulfur from the ocean to terrestrial regions, and it also affects atmospheric chemistry and the climate system. While they remain important, natural sulfur emissions have currently been overtaken by anthropogenic emissions, primarily from the burning of fossil fuels.

Although sulfur rarely becomes a limiting nutrient, its turnover is critical for ecosystem function. Organic sulfur compounds fuel microbial metabolism in the upper water column, and their turnover has important consequences, for example, for the climate system. Changes in the composition of phytoplankton and bacterioplankton due to global change could thus have dramatic, but as yet poorly understood, ramifications. Sulfur-metabolizing microorganisms also fulfill essential functions in their habitats by either degrading or forming biomass (organic carbon), as exemplified by the degrading activities of sulfate-reducing bacteria in marine sediments and the formation activities of sulfur-oxidizing bacteria at deep sea hydrothermal vents. Some sulfur-oxidizing bacteria further increase ecosystem productivity by retaining nitrogen and phosphorous compounds. In the future, it will be important to improve

quantitative estimates of these processes and to learn more about their interdependencies. Such knowledge will enable us to better assess their environmental impact and their possible responses to environmental changes.

See also: Biogeochemical Cycles.

Sulfur Dioxide

Sulfur dioxide (SO_2) is a gas produced from burning sulfur-containing fuels, mainly in thermal power plants. Some industrial processes, such as production of paper and smelting of metals, produce sulfur dioxide. It is a major contributor to smog and acid rain. Sulfur dioxide can lead to lung diseases.

Acid rain is a term which is used to describe a variety of processes which might more accurately be referred to as acidic deposition. The acid rain occurs when sulfur dioxide and nitrogen oxides from the burning of fossil fuels such as petrol, diesel, and coal combine with water vapor in the atmosphere and fall as rain, snow, or fog. These gases can also be emitted from natural sources like volcanoes. Acid rain causes extensive damage to water, forest, soil resources, and even human health. It is said that it can corrode buildings and be hazardous to human health. The international scope of the problem has led to the signing of international agreements on the limitation of sulfur and nitrogen oxide emissions.

See also: Combustion.

Sulfuric Acid Treating Process

The sulfuric acid treating process is a continuous or batch method that is used to remove sulfur compounds. The treatment will also remove asphaltic materials from various refinery stocks. The acid strength varies from fuming (>100 %) to 80%; approximately 93% acid finds the most common use. The weakest suitable acid is used for each particular situation to reduce sludge formation from the aromatic and olefin hydrocarbon derivatives.

The use of strong acid dictates the use of a fairly low temperature (-4 to 10°C , 25 to 50°F), but higher temperatures (20 to 55°C , 70 to 130°F) are possible if the product is to be redistilled.

Sun

As the major source that provides energy to the Earth, the energy source of the Sun, which is the closest star to Earth, deserves some attention.

The Sun's mean distance from the Earth is on the order of 92.96 million miles, and this distance is known as an astronomical unit (abbreviated AU), which establishes the scale for measuring distances all across the solar system. The Sun, a huge sphere of mostly ionized gas, supports life on Earth, and, moreover, the connection and interactions between the Sun and Earth drive the seasons, ocean currents, weather, and climate.

The Sun has no solid surface and is held together by gravitational attraction, producing immense pressure and temperature at its core and has six regions which are (i) the core, (ii) the radiative zone, (iii) the convective zone, (iv) the visible surface, which is also called the photosphere, (v) the chromosphere, and (iv) the outermost region, the corona. The Sun has no solid surface.

At the core, the temperature is on the order of $15,000,000^\circ\text{C}$ ($27,000,000^\circ\text{F}$), which is sufficient to sustain thermonuclear fusion. The energy produced in the core powers the Sun and produces essentially all the heat and light that are received by the Earth. Energy from the core is carried outward by radiation, which moves around the radiative zone, taking approximately 170,000 years to get from the core to the convective zone. The temperature drops below 2 million degrees Celsius (3.5 million degrees Fahrenheit) in the convective zone, where large bubbles of hot plasma (a soup of ionized atoms) move upwards. The photosphere 300-mile-thick region, from which most of the radiation of the Sun escapes outward and is detected as the sunlight that is observed on Earth approximately eight minutes after it leaves the Sun.

Sunspots in the photosphere are areas with strong magnetic fields that are cooler, and thus darker, than the surrounding region. Sunspot numbers fluctuate every 11 years as part of the Sun's magnetic activity cycle. Also connected to this cycle are bright solar flares and huge coronal mass ejections that blast off of the Sun. The temperature of the photosphere is on the order of 5,500°C (10,000°F). Above the photosphere lie the tenuous chromosphere and the corona, and the visible light from these top regions is usually too weak to be seen against the brighter photosphere, but during total solar eclipses, when the Moon covers the photosphere, the chromosphere can be seen as a red rim around the Sun while the corona forms a beautiful white crown with plasma streaming outward, forming the points of the crown.

Above the photosphere, temperature increases with altitude, reaching as high as 2,000,000°C (3,500,000°F). The source of coronal heating has been a scientific mystery for more than 50 years.

Sunflowers

Sunflowers are widely adapted in the United States but are most commonly grown in the western and northern Corn Belt. Sunflowers have been grown in localized areas of the Southeast for 15 or 20 years, primarily where there are specialty markets for the seed. Some cultivars of sunflowers have a short growing season, and the crop has potential in double-cropping scenarios either as the first or second crop.

Sunflower oil, extracted from the seeds, is used for cooking, as carrier oil, and to produce margarine and biodiesel. A range of sunflower varieties exist with differing fatty acid compositions. Some high oleic acid types contain a higher level of healthy monounsaturated fats in their oil than even olive oil.

Sunflower is a high oil content seed, and average yields can produce 600 pounds of oil per acre, considerably more than soybeans. There is a great deal of interest from local areas for construction of small processing facilities for sunflower biodiesel production. It is most important that processing equipment be analyzed very carefully for small press only facilities. In most cases, a portion of the oil is left in the by-product meal, thereby reducing economic efficiency.

Biodiesel can be produced from sunflower oil through a chemical process (transesterification). It is recommended that the sunflower oil be refined and de-waxed before blending it with diesel fuel.

See also: Biodiesel, Transesterification, Vegetable Oil.

Supercritical Fluid

A supercritical fluid is any substance at a temperature and pressure above the critical point where distinct liquid and gas phases do not exist, and which can effuse through solids like a gas and dissolve materials like a liquid.

Furthermore, there is no surface tension in a supercritical fluid, as there is no liquid/gas phase boundary. In addition, close to the critical point, small changes in pressure or temperature result in large changes in density, thereby allowing many properties of a supercritical fluid to be adjusted to be more liquid-like or more gas-like. All supercritical fluids are completely miscible with each other, so for a mixture, a single phase can be guaranteed if the critical point of the mixture is exceeded. The critical point of a binary mixture can be estimated as the arithmetic mean of the critical temperatures and pressures of the two components:

$$T_{c(mix)} = (\text{mole fraction } A) \times T_{cA} + (\text{mole fraction } B) \times T_{cB}$$

$T_{c(mix)}$ is the critical temperature of the mixture, A is component A , T_{cA} is the critical temperature of component A , B is component B , and T_{cB} is the critical temperature of component B . For greater accuracy, the critical point can be calculated using equations of state, and other properties, such as density, can also be calculated using equations of state.

Supercritical Fluid Extraction

Supercritical fluid extraction is the use as an extraction solvent of a material at a pressure and temperature above its vapor-liquid critical point. The process is very similar to liquid-liquid extraction. The critical point of the solvent is the temperature above which it cannot be liquefied, no matter how high the applied pressure. The corresponding vapor pressure at the critical temperature is called the critical pressure and is usually between 500 and 1,200 psig for light hydrocarbon gases, light freons, and carbon dioxide. The viscosity and diffusion properties of a supercritical solvent are much like those of a gas. However, the density, and thus the molecular interactions leading to solute solubility, are more like those of a liquid. These molecular interactions achieve the solubilization of high-molecular-weight solutes into a supercritical gas phase at temperatures well below the boiling point of the solute. This permits use of the supercritical gas as an extraction solvent for high-boiling-point heat-sensitive materials. It should be remembered that while this discussion is limited to the *extraction* application of supercritical fluids, once the solute is in the supercritical carrier phase, it can be treated by adsorbents, separated by chromatography, and subjected to other separation processes.

Most, if not all, of the separations possible with supercritical gas solvents could also be made with liquid solvents either well below or in the vicinity of their critical points. What is it then that drives the increasing application of supercritical gas extraction? It is the easier and less expensive solvent recovery, coupled with essentially complete solvent removal from the products, because of (i) the availability of non-toxic supercritical gas solvents such as carbon dioxide, (ii) the ability to process essentially non-volatile materials at moderate temperatures, and (iii) the low phase viscosities and high density differences between the phases, which enhance effective mass transfer and phase disengagement.

The solubility of solutes in the supercritical fluid increases as the density of the supercritical fluid is increased. Thus, operation at high pressure gives high solubilities in the supercritical solvent. Reduction of pressure on the supercritical gas phase decreases solubility and precipitates out part of the solute. This phenomenon can be used to perform intermediate fractionation of solute by reducing pressure in steps during solvent recovery. The supercritical solvent can be recovered from both the extract and raffinate merely by lowering pressure below the critical and letting the gaseous solvent flash off. Thus, by choosing a material having a low critical point, an effective extraction solvent of low viscosity, high solubilizing power, rapid mass transfer, and easy solvent recovery is obtained. The penalty for these benefits is the requirement for (i) operation at moderate-to-high pressure in pressure vessels and (ii) a compressor in the solvent recycle loop.

Relatively mild operating temperatures are possible for supercritical extractions using light hydrocarbons, light freons, or carbon dioxide as solvents. These range from 50 to about 120°C (250°F at pressures from 600 to several thousand psi). The use of water as a supercritical solvent requires temperatures above 430°C (705°F) and pressures above 3,200 psi. Thus, supercritical water finds more use as a medium for incineration by oxidation than as a solvent for extraction without conversion.

Super-Slagging Combustor

The super-slagging combustor invokes the concept of burning coal (to produce a low heat-content gas) within a bed of molten coal-ash slag fluxed with limestone; the sulfur in the coal reacts with the lime to form calcium sulfide. Thus, if such a super-slagging combustor were incorporated into a steam-generating boiler furnace with controlled addition of secondary air, the result might be a direct combustion system that produces flue gas with no sulfur or nitrogen oxides through staged combustion and maintains particulate emissions at a minimum. However, thermochemical calculations have shown that the product gas must be in equilibrium with excess carbon if sulfur is to be detained by the calcium oxide fluxed slag at 1,540°C (2,800°F) and that under even moderately oxidizing conditions, sulfur would not be absorbed. This has been demonstrated in preliminary tests where the sulfur in the product gas can be as little as of the sulfur in the feed gas.

See also: Combustion.

Surface Tension

Surface tension is a consequence of the imbalances in attractive forces between molecules and is related to the decrease in surface energy that results from decreasing surface area. At the surface, a layer forms in which the molecules are strongly bonded, thereby making it harder to penetrate the surface of the liquid than to move submersed objects. Stronger interactions between molecules result in higher values of surface tension, while lower values indicate that the molecules are not interacting as strongly. The dimensions for surface tension are expressed as force per unit length or energy per unit area. The surface tension of water is 72 dynes/cm at 25°C, indicating that it would take a force of 72 dynes to break a surface film of water 1 cm in length. Surface tension varies between liquids and is affected by temperature.

Surface tension is responsible for a broad range of phenomena. Surface tension impacts the shape of droplets, and allows for bubble formation.

Suspended Particulate Matter

Suspended particulate matter (SPM) is a general term used to describe particulate matter in gas streams, such as certain types of fine ash and dust. The particles are small pieces of matter measuring approximately 2.5 microns. One type of air pollution is the release of particles into the air from burning fuel for energy. Diesel smoke is a good example of this particulate matter. This type of pollution is sometimes referred to as black carbon pollution. The exhaust from burning fuels in automobiles, homes, and industries is a major source of pollution in the air.

See also: Particulate Matter.

Sustainability

Sustainability is an ecosystem condition in which biodiversity, renewability, and resource productivity are maintained. Thus, the term sustainability means meeting human needs without compromising the ability of future generations to meet their needs. In addition to natural resources, humans also need social and economic resources. In fact, sustainability is not just environmentalism, and embedded in the definition of sustainability, there are also considerations of social equity and economic development. In fact, while the concept of sustainability is a relatively new idea, the sustainability movement comes from the basics in social justice, conservationism, internationalism, and other past movements. By the end of the 20th century, many of these ideas had come together in the call for sustainable development.

In terms of environmental sustainability, ecological integrity is maintained; all of Earth's environmental systems are kept in balance, while the natural resources within them are consumed by humans at a rate where they are able to replenish themselves.

Economic sustainability means that human communities across the globe are able to maintain their independence and have access to the resources that they require, financial and other, to meet their needs. Economic systems are intact, and activities are available to everyone, such as secure sources of livelihood.

Finally, social sustainability is the concept that universal human rights and basic necessities are attainable by all people, who have access to enough resources in order to keep their families and communities healthy and secure. Healthy communities have just leaders who ensure personal, labor, and cultural rights are respected and all people are protected from discrimination.

Sweetening Processes

Many chemical processes are available for sweetening natural gas (Table S-4). For decades, the amine (olamine) process (also known as the Girdler process) has been the most widely used method for removal of hydrogen sulfide:

In this equation, R is mono, di, or tri-ethanol, N is nitrogen, H is hydrogen, and S is sulfur.

The recovered hydrogen sulfide gas stream may be: (1) vented, (2) flared in waste gas flares or modern smokeless flares, (3) incinerated, or (4) utilized for the production of elemental sulfur or sulfuric acid. If the recovered hydrogen sulfide gas stream is not to be utilized as a feedstock for commercial applications, the gas is usually passed to a tail gas incinerator in which the hydrogen sulfide is oxidized to sulfur dioxide and water for further processing of the sulfur dioxide.

Table S-4 Summary of the natural gas sweetening processes.

Iron-Sponge Sweetening
Reaction: $2\text{Fe}_2\text{O}_3 + 6\text{H}_2\text{S} \rightarrow 2\text{Fe}_2\text{S}_3 + 6\text{H}_2\text{O}$ Regeneration: $2\text{Fe}_2\text{S}_3 + 3\text{O}_2 \rightarrow 2\text{Fe}_2\text{O}_3 + 6\text{S}$ A batch process; most applicable for small gas volume with low content of hydrogen sulfide; operating temperature of the vessel <120°F (<49°C).
Alkanolamine Sweetening
Reaction: $\text{MEA} + \text{H}_2\text{S} \rightarrow \text{MEA-hydrosulfide} + \text{heat}$ $\text{MEA} + \text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{MEA-carbonate} + \text{heat}$ Regeneration: $\text{MEA-hydrosulfide} + \text{heat} \rightarrow \text{MEA} + \text{H}_2\text{S}$ $\text{MEA-carbonate} + \text{heat} \rightarrow \text{MEA} + \text{H}_2\text{O} + \text{CO}_2$ Alkanolamine: organic compounds including monoethanolamine (MEA), diethanolamine (DEA), and triethanolamine (TEA); not selective and have to be designed for total acid-gases removal; operating $p > 125$ psi for DEA; can absorb most of the acid gases and meet the specified pipeline requirement.
Glycol/Amine Process
A solution composed of 10-30% w/w MEA, 45-85% w/w glycol, and 5-25% w/w water for the simultaneous removal of water vapor, hydrogen sulfide, and carbon dioxide; the process flow scheme is essentially the same as that for MEA; applicable when low dew point is not required; there can be losses of MEA due to vaporization in the regeneration stage at high temperature.
Sulfinol Process
The solvent [composed of sulfolane, diisopropanolamine (DIPA), and water] acts as the physical (sulfolane) and chemical (DIPA) solvent; there is the benefit of low solvent circulation rates, smaller equipment, and lower cost; on the other hand, there can be absorption of high-molecular-weight hydrocarbon derivatives and aromatic derivatives.
Chemsweet Process and Zinc Oxide Process
Reaction: $\text{ZnAc}_2 + \text{H}_2\text{S} \rightarrow \text{ZnS} + 2\text{HAc}$, $\text{ZnO} + \text{H}_2\text{S} \rightarrow \text{ZnS} + \text{H}_2\text{O}$ Regeneration: $\text{ZnO} + 2\text{HAc} \rightarrow \text{ZnAc}_2 + \text{H}_2\text{O}$ Can be used to treat gas with a high concentration of hydrogen sulfide; operating p on the order of 89 to 1,415 psi; should not be used when the mercaptan concentration is in excess of 10% v/v hydrogen sulfide in the gas stream – mercaptans react with ZnO and forms Zn(OH)RH which will form a sludge and possibly cause foaming problems.

See also: Recovery Processes.

Sweet Potatoes

Sweet potatoes can produce 40% more alcohol per unit area than Jerusalem artichoke and two to four times as much as the other carbohydrate crops.

In addition to a high-yield capability, sweet potatoes have several other advantages. They can be planted and harvested mechanically and have good storage life so that an alcohol production facility could be supplied with feedstock over a period of several months. Many of the highest-yielding cultivars of sweet potatoes, including Jewel, are marketed for food and are also readily eaten by cattle. Thus, there could be considerable flexibility in marketing a sweet potato crop and in using those which might not find a ready sale. Dry weather at transplanting may hinder stand establishment unless irrigation is available. Harvesting is difficult unless sweet potatoes are grown on sandy or loamy soils.

Sweet potatoes have the ability to yield two to three times as much carbohydrate for fuel ethanol production as field corn grown in the same areas. In fact, the sweet potato carbohydrate yields approached the lower limits of those produced by sugarcane, the highest-yielding ethanol crop.

This leaves sweet potatoes with the potential to be a viable alternative as biofuel source. Although they require less pesticides and fertilizer than corn, planting and harvesting incur higher labor costs.

Switchgrass

Switchgrass (*Panicum virgatum*) is a perennial sod-forming grass with thick strong stems. It is a perennial warm season bunchgrass that is native to North America, where it occurs naturally from Canada southwards into the United States and Mexico. Switchgrass is one of the dominant species of the central North American tallgrass prairie and can be found in prairie remnants (grassland areas in the Western and Midwestern United States and Canada that remain, to some extent, undisturbed), in native grass pastures, and naturalized along roadsides. There are, in fact, many perennial crops (grass and tree species) that show high potential for production of cost-competitive cellulosic biomass. The “best” crop for a given area can only be determined by local soil and climate conditions and the desired end-use.

Switchgrass can be viewed as a surrogate for many “perennial energy crops” when doing biomass supply analysis. Other perennial energy crops that might be preferred in some situations include other thin-stemmed grasses, such as Reed Canary grass or Big Bluestem grass, or thick-stemmed grasses with rhizomes, such as *Miscanthus*, Energy cane, or *Arundo* (all may sometimes be marketed as E-Grass); trees grown as single stem row crops, such as poplars, eucalyptus, silver maple, sweetgum, and sycamore, or trees grown as multiple stem row crops such as willow or poplar coppice. Some annual crops are also being evaluated as dedicated energy crops including corn, sorghum, and kenaf (a woody annual crop), because of high yields. The perennial crops will normally show better environmental performance due to lower chemical requirements and better erosion control. The cost of production of energy crops is sensitive to yield; thus, the development of better energy crops involves traditional genetic selection and/or molecular genetics. It is also extremely important to select appropriate sites and optimize agronomic or silvi-cultural management techniques to eliminate weed competition and assure that adequate nutrients and water are available (but without overfertilizing or irrigating).

The advantages of switchgrass as an energy crop are that it is fast-growing, remarkably adaptable, and high-yielding. Further advantages of Switchgrass are that it can be harvested, using conventional equipment, either annually or semi-annually for 10 years or more before replanting is needed and that it is able to reach deep into the soil for water and use water very efficiently. Further advantages of switchgrass are that it can be harvested, using conventional equipment, either annually or semi-annually for 10 years or more before replanting is needed and that it is able to reach deep into the soil for water and use water very efficiently. Besides showing great promise as an energy crop for energy production, switchgrass also restores vital organic nutrients to farmed-out soils, and with its extensive network of stems and roots (the plants extend nearly as far below ground as above), it is also a valuable soil stabilization plant.

Switchgrass has the potential to be a versatile bioenergy feedstock since the energy content is comparable to that of wood with significantly lower initial moisture content. Switchgrass is very suitable substrate and produces high ethanol yield using current simultaneous saccharification and fermentation technology. Extensive analysis of ash and alkali content of switchgrass indicates that it typically has relatively low alkali content and should have low slagging potential in coal-fired combustion systems. As an agro-fiber source for pulping, switchgrass has a relatively high cellulose content, low ash content, and good fiber length-to-width ratios. Switchgrass reaches its full yield potential after the third year planted, producing approximately 6 to 8 tons per acre; that is 500 gallons of ethanol per acre.

The utilization of energy crops such as *switchgrass* (*Panicum virgatum* L., Poaceae) is a concept with great relevance to current ecological and economic issues on a global scale. Development of a significant national capacity to utilize perennial forage crops, such as switchgrass as biofuels, could provide an important new source of energy from perennial cropping systems, which are compatible with conventional farming practices, and would help reduce degradation of agricultural soil.

Synthesis Gas

Synthesis gas (also called syngas) is a mixture of carbon monoxide (CO) and hydrogen (H₂) that is manufactured by steam reforming natural gas. Some carbon dioxide is almost always inevitably produced.

This gas is an extremely important precursor for the synthesis of methanol, hydrogen, ammonia and other products. In particular, methane can be converted to synthesis gas and naphtha can then be produced from this mixture by the Fischer-Tropsch process. Naphtha is currently produced in Sasol, South Africa and in Malaysia using this technology. Methanol can be produced from synthesis gas using the methanol-to-gasoline (MTG) process:

The synthesis gas produced using existing methods accounts for approximately 60% of the total conversion cost of natural gas to gasoline. Thus, natural gas is an excellent candidate as an abundant alternative energy source.

The trend to increase the number of hydrogenation (hydrocracking and/or hydrotreating) processes in refineries coupled with the need to process the higher-boiling oils, which require substantial quantities of hydrogen for upgrading, has resulted in vastly increased demands for this gas. Part of the hydrogen needs can be satisfied by hydrogen recovery from catalytic reformer product gases, but other external sources are required. Most of the external hydrogen is manufactured either by steam-methane reforming or by oxidation processes. However, other processes, such as steam-methanol interaction or ammonia dissociation, may also be used as sources of hydrogen. Electrolysis of water produces high-purity hydrogen, but the power costs may be prohibitive.

The steam-methane reforming is a continuous catalytic process that has been employed for synthesis gas production and in some refineries, hydrogen production over a period of several decades. The major reaction is the formation of carbon monoxide and hydrogen from methane and steam:

Higher-molecular-weight feedstocks (such as propane and other hydrocarbon constituents of natural gas) may also yield carbon monoxide and hydrogen that can be adjusted to fit the required ratio for synthesis gas:

That is,

In the actual process, the feedstock is first desulfurized by passage through activated carbon, which may be preceded by caustic and water washes. The desulfurized material is then mixed with steam and passed over a nickel-based catalyst (730–845°C, 1,350 to 1,550°F and 400 psi). Effluent gases are cooled by the addition of steam or condensate to approximately 370°C (700°F), at which point (if hydrogen is the desired product) carbon monoxide reacts with steam in the presence of iron oxide in a shift converter to produce carbon dioxide and hydrogen. The carbon dioxide is removed by amine washing; the hydrogen is usually a high-purity (>99%) material.

Another synthesis gas generation process is a continuous, non-catalytic process that produces carbon monoxide and hydrogen by partial oxidation of gaseous or liquid hydrocarbon derivatives. A controlled mixture of preheated feedstock and oxygen is fed to the top of the reactor, where carbon dioxide and steam are the primary products. A secondary reaction between the feedstock and the gases forms carbon monoxide and hydrogen.

If necessary for hydrogen production only, the effluent is then led to a shift converter with high-pressure steam, where carbon monoxide is converted to carbon dioxide with the concurrent production of hydrogen at the rate of 1 mole of hydrogen for every mole of carbon dioxide. Reactor temperatures vary from 1,095 to 1,480°C (2,000 to 2,700°F) and pressures from atmospheric to more than 1,500 psi. Gas purification depends on the use of the gas.

See also: Fischer-Tropsch, Synthesis Gas.

Synthesis Gas – Fermentation

Anaerobic bacteria are able to grow on synthesis gas components, thus forming acetate and ethanol. The bacteria conversion has the advantages of high selectivity, no thermal equilibrium (because of irreversible ingestion of synthesis gas), and fewer problems with catalyst poisoning.

The bacteria culture has to be able to convert carbon dioxide, carbon monoxide, and hydrogen into ethanol. Many of the organisms are either mesophiles or thermophiles with temperature optimums ranging from room temperature to 90°C (195°F). A fairly rich medium is typically required, but high operating temperatures, low carbohydrate levels, low pH, and high carbon monoxide levels (which are inhibitory to methanogens) reduce the risk of contamination.

In contrast to many other synthesis gas-based processes, synthesis gas fermentation performance is not tied to a specific ratio of hydrogen to carbon monoxide. While the organisms generally prefer carbon monoxide to hydrogen, both carbon monoxide and hydrogen/carbon dioxide mixtures can be simultaneously converted.

The bacterium *Clostridium ljungdahlii* can be used where the reactants are carbon dioxide, carbon monoxide, and hydrogen reacting in an aqueous phase where pressure is less than 30 psi and the temperature is 35 to 37°C (95 to 99°F).

The ratio between ethanol to acetate produced is dependent upon fermentation reaction conditions. The production of acetic acid leads to a decreased pH, together with a higher concentration of acetate ions. This inhibits the organisms, in order to avoid further inhibition as the organisms switch to ethanol production. The pH is normally kept at 4.5 in ethanol production.

With a hydrogen/carbon monoxide ratio of 2, the reaction indicates that water and ethanol are the only theoretical products, but the ratio is not of major importance as the bacteria prefer carbon monoxide. Additionally, carbon monoxide and hydrogen shift reactions to improve the ratio are thus not necessary. The ethanol is toxic to the bacteria, resulting in a need to hold the ethanol concentrations below 3% in the reactor.

The biocatalytic reaction has the advantages of high yields and a high selectivity. The only products are ethanol, carbon dioxide, and water, thus avoiding upgrading, cracking, or separating processes of lower-grade products.

See also: Fermentation, Synthesis Gas.

Synthesis Gas – Fischer-Tropsch Process

In principle, synthesis gas can be produced from any hydrocarbon feedstock, which include natural gas, naphtha, residual oil, crude oil coke, coal, biomass, and municipal or industrial waste. The product gas stream is subsequently purified (to remove sulfur, nitrogen, and any particulate matter) after which it is catalytically converted to a mixture of liquid hydrocarbon products. In addition, synthesis gas may also be used to produce a variety of products, including ammonia, and methanol.

Of all of the carbonaceous materials used as feedstocks for gasification process, coal represents the most widely used feedstocks and, accordingly, about which the knowledge base is voluminous. In fact, gasification of coal has been a commercially available proven technology (2013a, 2013b). The modern gasification processes have evolved from three first-generation process technologies: (i) Lurgi fixed bed reactor, (ii) high-temperature Winkler fluidized bed reactor, and (iii) Koppers-Totzek entrained flow reactor. In each case, steam/air/oxygen are passed through heated coal which may be a fixed bed, a fluidized bed, or entrained in the gas. Exit gas temperatures from the reactor are 500°C (930°F), 900 to 1,100°C (1,650 to 2,010°F), and 1300 to 1,600°C (2,370 to 2,910°F), respectively. In addition to the steam/air/oxygen mixture being used as the feed gases, steam/oxygen mixtures can also be used in which membrane technology and a compressed oxygen-containing gas is employed.

In addition, low-value or negative-value materials and wastes such as crude oil coke, refinery residua, refinery waste, municipal sewage sludge, biomass, hydrocarbon contaminated soils, and chlorinated hydrocarbon by-products have all been used successfully in gasification operations. In addition, synthesis gas is used as a source of hydrogen or as an intermediate in producing a variety of hydrocarbon products by means of the Fischer-Tropsch synthesis (Chadeesingh, 2011). In fact, gasification to produce synthesis gas can proceed from any carbonaceous material, including biomass and waste.

There are different sources for obtaining synthesis gas. It can be produced by steam reforming or partial oxidation of any hydrocarbon ranging from natural gas (methane) to crude oil residua. It can also be obtained by gasifying the carbonaceous feedstock to a medium Btu gas (medium Btu gas consists of variable amounts of carbon monoxide, carbon dioxide, and hydrogen and is used principally as a fuel gas).

The first step in the process is feedstock preparation which may include unit operations such as (i) size reduction, (ii) screening, and (iii) slurring. The design of the feedstock preparation section depends on the properties of the raw material feed and on the requirements of the gasification technology that is selected. For example, preparing any form of crude oil resid, biomass, or waste for gasification is different to the preparation of bituminous coal for the gasifier, and the type of gasifier suitable for the gasification may also (or more than likely) be feedstock dependent.

Once the feedstock is prepared for the gasifier, the major route for producing synthesis gas is the steam reforming of natural gas over a promoted nickel catalyst at temperatures on the order of 800°C (1,470°F):

In some countries, synthesis gas is mainly produced by steam reforming naphtha. Because naphtha is a mixture of hydrocarbon derivatives ranging approximately from C5 to C10, the steam reforming reaction may be represented using n-heptane:

As the molecular weight of the hydrocarbon increases (lower H/C feed ratio), the hydrogen/carbon monoxide (H_2/CO) product ratio decreases. The hydrogen/carbon monoxide product ratio is approximately 3 for methane, 2.5 for ethane, 2.1 for heptane, and less than 2 for heavier hydrocarbon derivatives. The non-catalytic partial oxidation of hydrocarbon derivatives is also used to produce synthesis gas, but the hydrogen/carbon monoxide ratio is lower than from steam reforming. In practice, this ratio is even lower than what is shown by the stoichiometric equation because part of the methane is oxidized to carbon dioxide and water. When resids are partially oxidized by oxygen and steam at 1,400 to 1,450°C (2,550 to 2,640°F) and pressures on the order of 11,500 to 13,000 psi, the gas consists of equal parts of hydrogen and carbon monoxide.

See also: Synthesis Gas, Synthesis Gas – Fermentation, Synthesis Gas – Production.

Synthesis Gas – Production

In addition to the fermentation process, the gasification to produce synthesis gas can proceed from almost any organic material, including renewable resources such as biomass and plastic waste. The chemistry of the process for producing synthesis gas can be represented simply as:

Thus:

The products designated as synthesis fuels include low-to-high-boiling hydrocarbon derivatives and methanol. Also, the high-boiling products (including wax products) can also be used as feedstocks for gas production.

In addition, the actual process is described as comprising three components: (i) synthesis gas generation, (ii) waste heat recovery, and (iii) gas processing. Within each of the above three listed systems are several options. For example, synthesis gas can be generated to yield a range of compositions ranging from high-purity hydrogen to high-purity carbon monoxide. Two major routes can be utilized for high-purity gas production: (i) pressure swing adsorption and (ii) utilization of a cold box, where separation is achieved by distillation at low temperatures. In fact, both processes can also be used in combination as well. Unfortunately, both processes require high capital expenditure. However, to address these concerns, research and development are ongoing, and successes can be measured by the demonstration and commercialization of technologies such as permeable membrane for the generation of high-purity hydrogen, which in itself can be used to adjust the hydrogen/carbon monoxide ratio of the synthesis gas produced.

The resulting synthesis gas burns cleanly into water vapor and carbon dioxide or, alternatively, the gas may be converted to methane via the Sabatier reaction as well as to or to a kerosene liquid via the Fischer-Tropsch process. Inorganic components of the feedstock, such as metals and minerals, are trapped in an inert and environmentally safe form as a carbonaceous char that may be used as a fertilizer. The synthesis gas produced in large waste-to-energy gasification facilities is used as fuel to generate electricity.

A modified version of steam reforming known as autothermal reforming, which is a combination of partial oxidation near the reactor inlet with conventional steam reforming further along the reactor, improves the overall reactor efficiency and increases the flexibility of the process. Partial oxidation processes using oxygen instead of steam also found wide application for synthesis gas manufacture, with the special feature that they could utilize low-value feedstocks such as heavy crude oil residua. In recent years, catalytic partial oxidation employing short reaction times (milliseconds) at high temperatures (850 to 1,000°C; 1,560 to 1,830°F) is providing still another approach to synthesis gas manufacture. Nearly complete conversion of methane, with close to 100% selectivity to hydrogen and carbon dioxide, can be obtained with a rhenium monolith under well-controlled conditions. Experiments on the catalytic partial oxidation of *n*-hexane conducted with added steam give much higher yields of hydrogen than can be obtained in experiments without steam, a result of much interest in obtaining hydrogen-rich streams for fuel cell applications.

The route for a carbonaceous feedstock to synthetic automotive fuels, as practiced by SASOL, is technically proven, and a series of products with favorable environmental characteristics are produced. As is the case in essentially all conversion processes, for carbonaceous feedstocks where air or oxygen is used for the utilization or partial conversion of the energy in the coal, the carbon dioxide burden is a drawback as compared to crude oil.

The uses of synthesis gas include use as a chemical feedstock and in gas-to-liquid processes, which use Fischer-Tropsch chemistry to make liquid fuels as feedstock for chemical synthesis, as well as being used in the production of fuel additives, including diethyl ether and methyl *t*-butyl ether (MTBE), acetic acid, and its anhydride, synthesis gas

could also make an important contribution to chemical synthesis through conversion to methanol. There is also the option in which stranded natural gas is converted to synthesis gas production followed by conversion to liquid fuels.

Synthesis Gas – Products

Synthesis gas is an important intermediate. The mixture of carbon monoxide and hydrogen is used for producing methanol and a host of other products. Synthesis gas is also used to synthesize a wide variety of hydrocarbon derivatives ranging from gases to naphtha to gas oil using Fischer-Tropsch technology. This process may offer an alternative future route for obtaining olefin derivatives and chemicals.

Synthesis gas is a major source of hydrogen, which is used for producing ammonia. Ammonia is the host of many chemicals such as urea, ammonium nitrate, and hydrazine. Carbon dioxide, a by-product from synthesis gas, reacts with ammonia to produce urea (H_2NCONH_2).

Urea (also known as carbamide) serves an important role in the metabolism of nitrogen-containing compounds by animals and is the main nitrogen-containing substance in the urine of mammals. It is a colorless, odorless solid, highly soluble in water, and, dissolved in water, it exhibits neither an acid nor an alkali. It is formed in the liver by the combination of two ammonia molecules (NH_3) with a carbon dioxide (CO_2) molecule. It is widely used in fertilizers as a source of nitrogen and is an important raw material for the chemical industry.

Most of the production of hydrocarbon derivatives by the Fischer-Tropsch method uses synthesis gas produced from sources that yield a relatively low hydrogen/carbon monoxide ratio, such as typical in coal gasifiers. This, however, does not limit this process to low hydrogen/carbon monoxide gas feeds. The only large-scale commercial process using this technology is in South Africa, where coal is an abundant energy source. The process of obtaining liquid hydrocarbon derivatives from coal through the Fischer-Tropsch process is termed indirect coal liquefaction which was originally intended for obtaining liquid hydrocarbon derivatives from solid fuels. However, this method may well be applied in the future to the manufacture of chemicals through cracking the liquid products or by directing the reaction to produce more olefin derivatives.

The reactants in Fischer-Tropsch processes are carbon monoxide and hydrogen. The reaction may be considered a hydrogenative oligomerization of carbon monoxide in presence of a heterogeneous catalyst. The main reactions occurring in Fischer-Tropsch processes are:

(i) Olefin derivatives:

(ii) Paraffin derivatives:

(iii) Alcohol derivatives:

The coproduct water reacts with carbon monoxide (the shift reaction), yielding hydrogen and carbon dioxide:

The gained hydrogen from the water shift reaction reduces the hydrogen demand for Fischer-Tropsch processes. Water-gas shift proceeds at approximately the same rate as the Fischer-Tropsch reaction. Another side reaction also occurring in Fischer-Tropsch process reactors is the disproportionation of carbon monoxide to carbon dioxide and carbon:

This reaction is responsible for the deposition of carbon in the reactor tubes in fixed-bed reactors and reducing heat transfer efficiency.

Fischer-Tropsch technology is best exemplified by the SASOL projects in South Africa. After the carbonaceous feedstock is gasified to a synthesis gas mixture, it is purified in a Rectisol unit. The purified gas mixture is reacted in a Synthol unit over an iron-based catalyst. The main products are gasoline, diesel fuel, and jet fuels. By-products are ethylene, propylene, alpha olefin derivatives, sulfur, phenol, and ammonia which are used for the production of downstream chemicals. However, the exact mechanism is not fully established. One approach assumes a first-step adsorption of carbon monoxide on the catalyst surface followed by a transfer of an adsorbed hydrogen atom from an adjacent site to the metal carbonyl (M-CO). The polymerization continues (as in the last three steps shown above) until termination occurs and the hydrocarbon is desorbed. The last two steps shown above explain the presence of oxygenated derivatives in Fischer-Tropsch products.

Alternatively, an intermediate formation of an adsorbed methylene on the catalyst surface through the dissociative adsorption of carbon monoxide has been considered. The formed metal carbide (M-C) is then hydrogenated to a reactive methylene metal species. The methylene intermediate abstracts a hydrogen and is converted to an adsorbed methyl. Reaction of the methyl with the methylene produces an ethyl-metal species. Successive reactions of the methylene with the formed ethyl produce a long chain-adsorbed alkyl. The adsorbed alkyl species can either terminate to a paraffin by a hydrogenation step or to an olefin by a dehydrogenation step. The carbide mechanism, however, does not explain the formation of oxygenate derivatives in Fischer-Tropsch products.

Gas-to-liquids processing is similar to oil refining, since a number of products is obtained (Table S-5). Thus, gas-to-liquids synthesis can be regarded as an alternative refinery, run on feedstocks other than oil – natural gas, coal, or biomass. The total energy efficiency of gas-to-liquids processing is lower than that of oil refining (80% versus 85 to 90%), but the 20% gas-to-liquids thermal losses can be partly recovered via heat integration in the process units.

Table S-5 Examples of products from synthesis gas.

	Primary products	Secondary products
Synthesis gas	Ammonia	Amines Fertilizers
	Butanol	Butylene
	Ethanol	Aldehydes Ethylene Ketones
	Hydrocarbons	Naphtha (gasoline) Kerosene (diesel fuel)
	Methanol	Acetic acid Dimethyl ether Formaldehyde
	Olefins	Polymers
	Propanol	Propylene
	Wax	

Gas-to-liquids processing has an important technological difference with oil refining. The optimum oil refining output by fractions is spread among a number of products, is relatively constant, and can vary within relatively narrow margins. Conversely, the optimum breakdown of fractions in gas-to-liquids synthesis is more flexible and can be optimized to a larger extent versus certain products, most often versus middle distillates. Another feature of gas-to-liquids processing is that the higher-boiling fractions consist of high-quality lubricants and waxes ($<C_{20}$), but not of high-boiling fuel oils like in oil refining.

Gas-to-liquids lubricants and waxes could find a ready market, including in the food industry, while the market for high-boiling fuel oils is generally less profitable, along with the environmental burdens they cause. An additional and important environmental advantage of gas-to-liquids products is that, unlike oil derivatives, they are quickly biodegradable – the degradation rate of gas-to-liquids diesel reaches 60% within only 28 days in anaerobic conditions.

Gas-to-liquids products consist almost entirely of linear paraffins ($C_n H_{2n+2}$), with less than 5% aromatics on mass basis, compared to 10 to 30% aromatic derivatives for crude oil-derived products. Since paraffins have higher hydrogen-to-carbon ratio than aromatics, this implies lower density and higher energy content on a weight basis for gas-to-liquids fuels compared to oil-based fuels. Due to the lower density, the volumetric energy content of gas-to-liquids products is however lower than that of oil derivatives. In addition, linear paraffins are more easily and efficiently transformed into other products than aromatics and branch paraffins.

Finally, all gas-to-liquids products are virtually sulfur-free (sulfur content: <1 ppm), since a large part of sulfur compounds is removed during the synthesis gas production step. The remaining small traces of sulfur are further separated before the gas-to-liquids synthesis, because the catalysts for GTL processing are extremely sensitive even to low contaminations of sulfur.

Synthesis Gas – Quality

The various technologies are (i) bubbling fluidized bed, (ii) circulating fluidized bed, and (iii) indirectly heated gasifiers.

The indirectly fired gasifiers produce the highest heating value synthesis gas ranging from 320 to 485 Btu/ft³ using air. As far as power generation using synthesis gas is concerned, the high heating value with less tar component is more important than the composition of the synthesis gas, however, for other applications such as synfuel, methanol production, and the hydrogen/carbon monoxide ratio. In general, indirectly heated gasifiers generate synthesis gas with a high percentage of hydrogen, methane, and C_{2+} compounds which directly contribute for the higher heating value of the synthesis gas. Similarly, for the directly fired gasifiers, the higher range of hydrogen, methane, and C_{2+} components correspond to the combustion using oxygen, leading to a higher calorific value of the synthesis gas. The absence of nitrogen (inert) in the system largely helps to concentrate the composition of synthesis gas with higher heating value components. Production of tars, chars, and volatile alkalis are problems associated with gasification which requires further cleaning before utilized in turbines for power generation.

The product stream at high pressure and temperature needs to be cleaned under hot conditions not lower than 540°C (1,005°F) (tar dew point) in order to maximize the energy conversion efficiency. Thus, a hot clean-up system is required, for which either catalytic tar crackers or a thermal tar cracker could be utilized. A catalytic tar reformer will operate at temperatures comparable to gasifier temperature of 825°C (1,515°F), while a thermal cracker will typically operate at 870 to 980°C (1,600 to 1,795°F). After the tar reformer/cracker, the product gas will be partially cooled to minimize the amount of alkali vapors, typically to 350–650°C. The product will then pass through a filter to remove solids. As gas turbine application limits the alkali to less than 25 ppb, much of alkali as well needs to be removed.

Synthetic Fuels

Gaseous or liquid synthetic fuels are obtained by converting a carbonaceous material to another form. In the United States, the most abundant naturally occurring materials suitable for this purpose are coal, tar sand, and oil shale. The

conversion of these raw materials is carried out to produce synthetic fuels to replace the depleted, unavailable, or costly supplies of natural fuels. However, the conversion may also be undertaken to remove sulfur or nitrogen that would otherwise be burned, giving rise to undesirable air pollutants. Another reason for conversion is to increase the calorific value of the original raw fuel by removing unwanted constituents such as ash, and thereby to produce a fuel which is cheaper to transport and handle.

Biomass can also be converted to synthetic fuels, and the fermentation of grain to produce alcohol is a well-known example. In the United States, grain is an expensive product which is generally thought to be more useful for its food value. Wood is an abundant and accessible source of bio-energy, but it is not known whether its use to produce synthetic fuels is economical. The procedures for the gasification of cellulosic materials have much in common with the conversion of coal to gas, and options are available for the use of the products.

Generally, the more hydrogen that is added to the raw material, the lower the boiling point of the synthesized product. Also, the more hydrogen that must be added, or alternatively the more carbon which must be removed, the lower the overall conversion efficiency in the manufacture of the synthetic fuel.

Synthetic fuels include low-, medium-, and high-calorific value gas; liquid fuels such as naphtha, kerosene, fuel oil, and clean solid fuels. Low-heat content gas is an ideal turbine fuel whose greatest utility will probably be in a gas-steam combined power cycle for the generation of electricity at the location where it is produced.

Medium Btu gas is also termed power gas or sometimes industrial gas, as well as synthesis gas. It may be used as a fuel gas, as a source of hydrogen for the direct liquefaction of coal to liquid fuels, or for the synthesis of methanol and other liquid fuels. Medium Btu gas may also be used for the production of high Btu gas, and is normally composed of more than 90% methane. Because of its high calorific value, this gas is a substitute for natural gas and is suitable for economic pipeline transport. For these reasons, it is referred to as substitute natural gas (SNG) or pipeline gas.

Gas can be manufactured by indirect hydrogenation by reacting steam with the feedstock either in the presence of air or oxygen. When air is used, the product gas will be diluted with nitrogen and its calorific value will be low in comparison with the gas manufactured using oxygen. The dilution of the product gas with nitrogen can be avoided by supplying the heat needed for the gasification from a hot material that has been heated with air, in a separate furnace, or in the gasifier itself before gasification. In all of the cases, the gas must be cleaned prior to using it as a fuel. This purification step involves the removal of the hydrogen sulfide, ammonia, and carbon dioxide, which are products of the gasification. Medium Btu gas, consisting mainly of carbon monoxide and hydrogen, can be further upgraded by altering the carbon monoxide-to-hydrogen ratio catalytically and then, in another catalytic step, converting the resulting synthesis gas mixture to methane. A high Btu gas can be produced by direct hydrogenation, termed hydrogasification, in which hydrogen is contacted with the coal.

Catalytic gasification accelerates the steam gasification of coal at relatively low temperatures and also catalyzes the upgrading and methanation reactions at the same low temperature in the same unit. Gas can also be produced by pyrolysis, that is, by the distillation of the volatile components.

Clean synthetic liquid fuels can be produced by several routes, depending on the properties and character of the feedstock. For example, in indirect liquefaction, the feedstock is first gasified, and then the liquid fuel is synthesized from the gas. This procedure is not thermally efficient, relating to the fact that the carbon bonds in the feedstock must first be broken, as in gasification, and then in a further step, some of them must be put back together again.

Another procedure is pyrolysis, the distillation of the natural oil out of the feedstock. The oil vapors are condensed, the resulting pyrolysis oil is treated with hydrogen, and the sulfur and nitrogen in it are reduced. This is similar to the procedure used in upgrading crude oil in a refinery to produce a variety of liquid fuels. Pyrolysis may also be carried out in a hydrogen atmosphere, a process termed hydrolysis, in order to increase the liquid and gas yield.

In direct liquefaction, there are two basic procedures, hydroliquefaction and solvent extraction. In the hydroliquefaction process, the feedstock is mixed with recycled oil and, together with hydrogen, fed to a high-pressure catalytic reactor where the hydrogenation of the feedstock takes place. In solvent extraction (solvent refining), the feedstock and the hydrogen are dissolved at high pressure in a recycled feedstock-derived solvent which transfers the hydrogen to the feedstock. After phase separation, the liquid product is cleaned and upgraded by refinery procedures to produce liquid fuels. In solvent refining, with a low level of hydrogen transfer, a solid, relatively clean fuel is obtained.

Synthetic Fuels – Production

The process of producing synfuels is often referred to as coal-to-liquids (CTL), gas-to-liquids (GTL), or biomass-to-liquids (BTL), depending on the initial feedstock.

Gas to liquids is a process for conversion of natural gas into longer-chain hydrocarbon derivatives. Thus, methane-rich gases are converted into liquid fuels either via direct conversion or via synthesis gas as an intermediate, for example using the Fischer-Tropsch process. Using such processes, refineries can convert some of their gaseous waste products into valuable fuel oils, which can be sold as or blended only with diesel fuel. The process may also be used for the economic extraction of gas deposits in locations where it is not economic to build a pipeline.

The best known synthesis process is the Fischer-Tropsch synthesis which was used on a large scale in Germany during World War II. Other processes include the Bergius process, the Mobil process, and the Karrick process. An intermediate step in the production of synthetic fuel is often synthesis gas, a stoichiometric mixture of carbon monoxide and hydrogen, which is sometimes directly used as an industrial fuel.

Several factors do make fuels from renewable sources attractive relative to conventional crude oil-based fuels. For example, the renewable source is available in quantities sufficient to meet current demand for centuries. In addition, many of the raw materials can produce naphtha or kerosene directly without the need for additional refining steps such as reforming or cracking. In some cases, there is no need to convert vehicle engines to use a different fuel and, moreover, the distribution network is already in place.

However, with higher costs of production and higher risks, companies may be well inclined to seek tax credits for the production of synthetic fuels from non-conventional sources. In allowing these credits, governments will be well advised to consider the value of a measure of energy independence.

Canada asked this question in the 1970s with respect to the development of the Athabasca oil sands (tar sands) located in north-eastern Alberta. As a result, production is now 1,000,000 bbls/day of synthetic crude oil which makes a considerable difference to the imports of non-domestic crude oil by Canada.

Synthetic Gas

As opposed to natural gas which is produced over geological time by the decay of organic material, synthetic gas is any gas that is produced by processes other than natural processes.

The increasing demand for natural gas and fluctuation natural gas prices in the recent past has led many to pursue unconventional methods of alternate sources of gaseous fuels. In one particular aspect of gas production, biogas from biomass is expected to become increasingly important in the future. In fact, there are two major approaches to convert biomass into gas which are (i) fluidized bed gasification with subsequent catalytic reforming, both operating around 900°C (1,650°F), and (ii) entrained flow gasification at approximately 1,300°C (2,370°F) with extensive pre-treatment.

The fluidized bed gasification of biomass approach has the advantage that the gasification technology has been developed for the production of heat and/or electricity. In addition, entrained flow gasification processes have already been developed. However, the biomass feedstock, however, needs to be pre-treated in order to take full advantage of these technologies. Pretreatment is necessary and focuses on pre-treatment such as flash pyrolysis and production of a high energy density slurry and torrefaction for the production of a suitable feedstock. Close-coupled pre-treatment options include slow pyrolysis (500°C, 930°F) and followed by choice of the gasification process.

Synthetic Gas – Biogas

Biogas, sometimes incorrectly known as swamp gas, typically refers to a biofuel gas produced by anaerobic digestion or fermentation of organic matter including manure, sewage sludge, municipal solid waste, biodegradable waste, or

any other biodegradable feedstock, under anaerobic conditions. Depending on where it is produced, biogas is also called swamp gas, marsh gas, landfill gas, and digester gas.

Biogas is produced by means of anaerobic digestion which is a process whereby organic matter is broken down by microbiological activity, and, as the name suggests, it is a process which takes place in the absence of air. It is a phenomenon that occurs naturally at the bottom of ponds and marshes and gives rise to marsh gas or methane, which is a combustible gas. There are two common man-made technologies for obtaining biogas; the first (which is more widespread) is the fermentation of human and/or animal waste in specially designed digesters. The second is a more recently developed technology for capturing methane from municipal waste landfill sites. The digestion of animal and human waste yields several benefits: (i) the production of methane for use as a fuel, (ii) the waste is reduced to slurry which has a high nutrient content which makes an ideal fertilizer which, in some cases, is the main product from the digester and the biogas is merely a by-product, and (iii) during the digestion process, bacteria in the manure are killed, which is a great benefit to environmental health.

In the process, the waste is fed into the digester via the inlet pipe and undergoes digestion in the digestion chamber. The temperature of the process is quite critical – methane-producing bacteria operate most efficiently at temperatures between 30 and 40°C (86 to 104°F) or 50 and 60°C (122 to 140°F), and in colder climates, heat may have to be added to the chamber to encourage the bacteria to carry out their function. The product is a combination of methane and carbon dioxide, typically in a ratio on the order of 6:4. Digestion time ranges from a couple of weeks to a couple of months depending on the feedstock and the digestion temperature. The residual slurry is removed at the outlet and can be used as a fertilizer.

The composition of biogas varies depending upon the composition of the waste material in the landfill and the anaerobic digestion process. Landfill gas typically has methane concentrations around 50%. Advanced waste treatment technologies can produce biogas with 55 to 75% v/v methane; often, air is introduced (equivalent to 5% v/v) for microbiological desulfurization. For example, the constituents of biogas generally are methane (50 to 75% v/v), carbon dioxide (25 to 50% v/v), nitrogen (0 to 10% v/v), hydrogen (0 to 1% v/v), hydrogen sulfide (0 to 3% v/v), and oxygen (0 to 2% v/v).

If biogas is cleaned by any one of a variety of relevant processes, the product gas has the same characteristics as natural gas. In this instance, the producer of the biogas can utilize the local gas distribution networks. The gas must be clean to reach pipeline quality. Water (H₂O), hydrogen sulfide (H₂S), and particulates are removed if present at high levels or if the gas is to be completely cleaned. Carbon dioxide is less frequently removed, but it must also be separated to achieve pipeline-quality gas. If the gas is to be used without extensively cleaning, it is sometimes co-fired with natural gas to improve combustion. Biogas cleaned up to pipeline quality is called *renewable natural gas*. In this form, the gas can be used in any application in which natural gas is used.

Biogas is almost identical to natural gas (methane, CH₄). The equation for the complete combustion of methane is given:

Natural gas, which is generally found associated with fossil fuels, coal, and gas hydrates (clathrates of methane in ice crystals), may also contain small amounts of ethane, propane, butane, and pentane, which are higher-boiling hydrocarbon derivatives removed prior to use as a consumer fuel, as well as carbon dioxide, nitrogen, helium, and hydrogen sulfide. Biogas is produced by methanogenic organisms in landfills, swamps, and marshes, by the decomposition of organic (both animal and plant) matter. The anaerobic (low or no oxygen present in the system) decomposition produces methane, carbon dioxide, a small amount of hydrogen, and a small amount of heat. Acidity, the carbon-to-nitrogen ratio of the feedstock, temperature, and percentage of solids all influence the quality and quantity of biogas produced. Normally, cow manure, enriched by vegetable matter, is the ideal feedstock. The other principal type of biogas is wood gas which is created by gasification of wood or other biomass. This type of biogas is comprised primarily of nitrogen, hydrogen, and carbon monoxide, with trace amounts of methane. Industrial anaerobic digesters and mechanical biological treatment systems are becoming increasingly popular. Methane is a potent greenhouse gas but is also a clean, easy burning fuel, and hence harnessing it from natural sources such as landfills is beneficial to the natural environment.

Finally, high-temperature gasification supplies a crude gas, which may be transformed into hydrogen by a second reaction step. In addition to biogas, there is also the possibility of using the solid by-product as a biofuel. The technologies for gas production from biomass include: (i) fermentation, (ii) gasification, and (iii) direct biophotolysis.

Synthetic Gas – Blue Water Gas

Blue water gas (also called blue gas) is a gas consisting mainly of carbon monoxide and hydrogen, made by passing steam over red-hot coke and burning with a blue flame, used especially as a source of hydrogen.

The constituents of the gas are predominantly carbon monoxide and hydrogen, formed by the action of steam upon hot coke; used mainly as a source of hydrogen and in the synthesis of other chemical compounds. The gas is used as a fuel gas used in the industrial synthesis of organic chemicals, and in welding, glassmaking, and other high-temperature industrial applications.

Water gas is made by passing steam over a bed of hot coal or coke. It mainly consists of carbon monoxide (CO) and hydrogen (H₂), contaminated with small amounts of carbon dioxide (CO₂), nitrogen (N₂), methane (CH₄), and oxygen (O₂).

See also: Synthetic Gas – Water Gas.

Synthetic Gas – Carbureted Water Gas

Carbureted water is a water gas that has been enriched by mixing the water gas hydrocarbon gases to increase the fuel value.

The process for manufacturing carbureted water gas consists of a single generator having a bed of solid fuel, a single carburetor, a single superheater, a regenerator containing a body of refractory and heat-accumulative material, and a gas offtake seal. The process involves air blasting the generator fuel bed, conducting the resultant gas through the carburetor and superheater, and burning it to heat the same. The gas is subsequently passed back through the superheater and carburetor and then downward through the generator fuel bed, conducting the hot back-run water gas produced through the regenerator to heat the same and cool said gas. Back-run gas is then passed through the gas offtake seal at intervals subsequent to the air-blasting and back-steaming period while passing steam through the said heated regenerator, conducting resultant uprun water gas through the heated carburetor and superheater and carbureting it during its passage through said carburetor and superheater by introducing oil.

See also: Carbureted Blue, Gas, Synthetic Gas – Water Gas.

Synthetic Gas – High Btu Gas

High Btu gas (high heat-content gas) is essentially pure methane and often referred to as synthetic natural gas or substitute natural gas (SNG). However, to qualify as substitute natural gas, a product must contain at least 95% v/v methane, giving an energy content (heat content) of synthetic natural gas on the order of 980 to 1080 Btu/ft³.

The commonly accepted approach to the synthesis of high heat-content gas is the catalytic reaction of hydrogen and carbon monoxide:

To avoid catalyst poisoning, the feed gases for this reaction must be quite pure, and, therefore, impurities in the product are rare. The large quantities of water produced are removed by condensation and recirculated as very pure

water through the gasification system. The hydrogen is usually present in slight excess to ensure that the toxic carbon monoxide is reacted; this small quantity of hydrogen will lower the heat content to a small degree.

The carbon monoxide/hydrogen reaction is somewhat inefficient as a means of producing methane because the reaction liberates large quantities of heat. In addition, the methanation catalyst is troublesome and prone to poisoning by sulfur compounds and the decomposition of metals can destroy the catalyst. Hydrogasification may be thus employed to minimize the need for methanation:

The product of hydrogasification is far from pure methane, and additional methanation is required after hydrogen sulfide and other impurities are removed.

Synthetic Gas – Hydrogen

Hydrogen is one of the basic raw materials for technological processes, including refinery processes, and will continue to play a major role for the foreseeable future (2019). In the refinery, hydrogen is produced by any one (or more) of several processes, not the least of which is the production of hydrogen from synthesis gas. Other methods, in the context of this book, include (i) steam methane reforming, (ii) biomass pyrolysis, and (iii) biomass gasification.

Steam methane reforming (SMR) is a process requiring high temperature and pressure. During the process, hydrogen is generated in reactions with methane/CO and water participation under pressure:

The process requires catalysts from nickel or nickel alloy. The gas needs to be desulfurized to prevent catalyst poisoning.

The pyrolysis of biomass, reaction, is a thermal decomposition that depends on the properties of the biomass, the use of catalysts, and the temperature: The process achieved by rapid heating of organic wastes to high temperatures 400 to 600°C (750 to 1,120°F) and pressure. The products of the process are hydrogen, carbon monoxide, methane, tar, and oils. Optimally, hemicelluloses are degraded at temperatures on the order of 250 to 350°C (480 to 660°F), cellulose at temperatures on the order of 325 to 400°C (615 to 750°F), and lignin at temperatures on the order of from 300 to 550°C (570 to 1,020°F).

Biomass gasification is the decomposition of biomass using heat and gasifying agents (such as steam). The waste biomass useful for the process should have dry matter content higher than 65%. The catalysts proposed to be used are, e.g., dolomites, alkali catalysts, and noble metals. Temperature of process depends on the properties of the feedstock. The biomass feedstock is fragmented and dried. The catalysts proposed to be used are dolomite minerals, alkali catalysts, and noble metals.

Synthetic Gas – Landfill Gas

Landfill gas (LFG, sometimes referred to as refuse gas and, under the collective group, known as biogas) is produced by the microbial decomposition of landfilled waste in an oxygen-free (anaerobic) atmosphere. This generally occurs under semi-controlled conditions in a landfill; its constituents depend on the composition and age of the waste.

Landfill gas is, in fact, a fuel gas that is a by-product of current landfilling practices and hence occurs only after municipal solid waste has been sent for disposal to a landfill site. The anaerobic digestion of the buried solid organic waste produces the landfill gas naturally, as the bacterial decomposition of the organic matter continues over time. In the long run, as the use of landfills necessarily dwindles, landfill gas will disappear as a resource. It is thus of an inherently transient nature, but will be covered here as many examples of landfill gas plants exist.

The gas is approximately 65% v/v methane and 35% v/v carbon dioxide as well as traces of other organic vapors, but the composition of the gas does vary with age and the type of waste. The odor of landfill gas is associated with trace compounds such as hydrogen sulfide (H_2S or H-SH), mercaptan derivatives (RSH), and ethylene ($\text{CH}_2=\text{CH}_2$). In addition, there are several physical conditions that affect the production (the rate of production and the volume of the gas) of the gas, namely, (i) the characteristics of the waste, which is the composition and age of the refuse, as well as (ii) environmental factors, such as the presence of oxygen in the landfill, moisture content, and temperature. Other factors can affect the migration of the gas.

Synthetic Gas – Low-Btu Gas

Low Btu gas (low heat content gas) is produced during the process by oxidation of the feedstock with air; the oxygen is not separated from the air and, as a result, the gas product invariably has a low heat-content (150 to 300 Btu/ft³). Low heat-content gas is also the usual product of *in situ* gasification of coal which is essentially used as a method for obtaining energy from coal without the necessity of mining the coal, especially if the coal cannot be mined or if mining is uneconomical.

Several important chemical reactions and a host of side reactions are involved in the manufacture of low heat-content gas under the high temperature conditions employed. Low heat-content gas contains several components, four of which are always major components present at levels of at least several percent; a fifth component, methane, is marginally a major component.

The nitrogen content of low heat-content gas ranges from somewhat less than 33% v/v to slightly more than 50% v/v and cannot be removed by any reasonable means; the presence of nitrogen at these levels makes the product gas *low heat-content* by definition. The nitrogen also strongly limits the applicability of the gas to chemical synthesis. Two other noncombustible components (water, H_2O , and carbon dioxide, CO) further lower the heating value of the gas; water can be removed by condensation and carbon dioxide by relatively straightforward chemical means.

The two major combustible components are hydrogen and carbon monoxide; the H_2/CO ratio varies from approximately 2:3 to approximately 3:2. Methane may also make an appreciable contribution to the heat content of the gas. Of the minor components, hydrogen sulfide is the most significant and the amount produced is, in fact, proportional to the sulfur content of the feed coal. Any hydrogen sulfide present must be removed by one, or more, of several procedures.

Low heat-content gas is of interest to industry as a fuel gas or even, on occasion, as a raw material from which ammonia, methanol, and other compounds may be synthesized.

Synthetic Gas – Medium Btu Gas

Medium heat-content gas (medium heat-content gas) has a heating value in the range 300 to 550 Btu/ft³, and the composition is much like that of low heat-content gas, except that there is virtually no nitrogen. The primary combustible gases in medium heat-content gas are hydrogen and carbon monoxide (Kasem, 1979). Medium heat-content gas is considerably more versatile than low heat-content gas; like low heat-content gas, medium heat-content gas may be used directly as a fuel to raise steam, or used through a combined power cycle to drive a gas turbine, with the hot exhaust gases employed to raise steam, but medium heat-content gas is especially amenable to synthesize methane (by methanation), higher hydrocarbon derivatives (by Fischer-Tropsch synthesis), methanol, and a variety of synthetic chemicals.

The reactions used to produce medium heat-content gas are the same as those employed for low heat-content gas synthesis, the major difference being the application of a nitrogen barrier (such as the use of pure oxygen) to keep diluent nitrogen out of the system.

In medium heat-content gas, the H_2/CO ratio varies from 2:3 C to 3:1 and the increased heating value correlates with higher methane and hydrogen contents as well as with lower carbon dioxide contents. Furthermore, the very nature of the gasification process used to produce the medium heat-content gas has a marked effect upon the ease of subsequent processing. For example, the CO_2 -acceptor product is quite amenable to use for methane production

because it has (i) the desired H_2/CO ratio just exceeding 3:1, (ii) an initially high methane content, and (iii) relatively low water and carbon dioxide contents. Other gases may require appreciable shift reaction and removal of large quantities of water and carbon dioxide prior to methanation.

Synthetic Gas – Producer Gas

Producer gas is mainly carbon monoxide with smaller amounts of hydrogen, methane, and variable nitrogen, obtained from partial combustion of coal or coke in air or oxygen, having a heat content of 110 to 160 Btu/ft³ (air combustion) or 400 to 500 Btu/ft³ (oxygen combustion).

Materials such as glass and metals are removed during the treatment processing since they are non-combustible. Typically, the metals are removed using a magnet and the glass using mechanical.

See also: Gasification, Refuse.

Synthetic Gas – Refuse Gas

Refuse gas (also called refuse-derived fuel gas) consists largely of combustible components of such waste, as non-recyclable plastic waste (not including polyvinyl chloride paper, cardboard, labels, and other corrugated materials). The conversion of the refuse to gas is achieved by application of a thermal process.

Landfill gas is also a refuse gas, and three processes – (i) bacterial decomposition, (ii) volatilization, and (iii) chemical reactions – form landfill gas. Most landfill gas is produced by bacterial decomposition, which occurs when organic waste is broken down by bacteria naturally present in the waste and in the soil used to cover the landfill. Organic wastes include food, garden waste, street sweepings, textiles, and wood and paper products. Bacteria decompose organic waste in four phases, and the composition of the gas changes during each phase.

Landfill gases can be created when certain wastes, particularly organic compounds, change from a liquid or a solid into a vapor (volatilization). Non-methane organic compounds in landfill gas may be the result of volatilization of certain chemicals disposed of in the landfill. Finally, chemical reactions also produce landfill gas, including the formation of landfill gas, and including the formation of non-methane organic compounds, which can be created by the reactions of certain chemicals present in waste.

See also: Landfill Gas, Refuse Gas.

Synthetic Gas – Synthesis Gas

Synthesis gas is a mixture mainly of hydrogen and carbon monoxide which is comparable in its combustion efficiency to natural gas. This reduces the emissions of sulfur, nitrogen oxides, and mercury, resulting in a much cleaner fuel. The resulting hydrogen gas can be used for electricity generation or as a transport fuel. The gasification process also facilitates capture of carbon dioxide emissions from the combustion effluent (see discussion of carbon capture and storage below).

Although synthesis gas can be used as a stand-alone fuel, the energy density of synthesis gas is approximately half that of natural gas and is therefore mostly suited for the production of transportation fuels and other chemical products. Synthesis gas is mainly used as an intermediary building block for the final production (synthesis) of various fuels such as synthetic natural gas, methanol, and synthetic crude oil fuel (dimethyl ether – synthesized naphtha and kerosene).

The use of synthesis gas offers the opportunity to furnish a broad range of environmentally clean fuels and chemicals, and there has been steady growth in the traditional uses of synthesis gas. Almost all hydrogen gas is manufactured from synthesis gas, and there has been an increase in the demand for this basic chemical. In fact, the major use of synthesis gas is in the manufacture of hydrogen for a growing number of purposes, especially in crude oil refineries. Methanol not only remains the second largest consumer of synthesis gas but has shown remarkable growth as part of the methyl ethers used as octane enhancers in automotive fuels.

The Fischer-Tropsch synthesis remains the third largest consumer of synthesis gas, mostly for transportation fuels but also as a growing feedstock source for the manufacture of chemicals, including polymers. The hydroformylation of olefins (the Oxo reaction), a completely chemical use of synthesis gas, is the fourth largest use of carbon monoxide and hydrogen mixtures. A direct application of synthesis gas as fuel (and eventually also for chemicals) that promises to increase is its use for *integrated gasification combined cycle* (IGCC) units for the generation of electricity (and also chemicals) from coal, crude oil coke, or high-boiling crude oil residues (particularly vacuum residues). Finally, synthesis gas is the principal source of carbon monoxide, which is used in an expanding list of carbonylation reactions, which are of major industrial interest.

Synthetic Gas – Water Gas

Water gas (carbureted blue gas) is obtained by the reaction of steam with incandescent coke. Used first as a fuel, water gas soon attracted attention as a source of hydrogen and carbon monoxide for the production of chemicals, at which time it gradually became known as synthesis gas.

The water gas process is a process by which large amounts of hydrogen gas can be generated for residential and commercial use in heating and lighting. This gas provided a more efficient heating fuel than the common coal gas, or coke gas, which was used in municipal service. The process used the water-gas shift reaction:

The process spurred on the gas manufacturing industry, and gasification plants were established quickly along the Eastern seaboard of the United States.

Synthetic Gas – Wood Gas

Wood gas is a synthetic gaseous fuel which can be used as a fuel for furnaces, stoves, and vehicles in place of gasoline, diesel fuel, or other fuels. During the production process, biomass or other renewable carbon-containing source materials are gasified within the oxygen-limited environment of a wood gas generator to produce hydrogen and carbon monoxide. These gases can then be burnt as a fuel within an oxygen-rich environment to produce carbon dioxide, water, and heat. In some gasifiers, this process is preceded by a pyrolysis step in which biomass is first converted to char, releasing methane and a tar that is rich in polycyclic aromatic hydrocarbon derivatives.

The quality of the gas from different gasifiers varies considerably. In fact, the gas composition is strongly dependent on (i) the gasification process, (ii) the gasification medium (air, oxygen, or steam), and (iii) the moisture content of the feedstock. Steam-gasification processes typically yield high hydrogen contents; downdraft fixed bed gasifiers yield high nitrogen concentrations and low tar loads, while updraft fixed bed gasifiers yield high tar load.

Staged gasifiers, where pyrolysis and gasification occur separately, instead of in the same reaction zone as was the case in, for example, the gasifiers used in the World War II period, can be engineered to produce essentially tar-free gas (less than 1 mg/m³), while the gas single-reactor fluidized bed gasifiers may exceed 50,000 mg/m³ tar. The fluidized bed reactors have the advantage of being much more compact, with more capacity per unit volume and price. Depending on the intended use of the gas, tar can be beneficial, as well by increasing the heating value of the gas.

See also: Gasification, Synthesis Gas.

Synthol Process

The Synthol process is another process that has the potential to be applied to the production of fuels from biomass.

The process has been operated at commercial scale since the 1950s by Sasol to produce synthetic fuels from coal and has undergone some evolution. The initial process, the Arge Process, involved low temperatures (200-250°C),

medium pressures, and a fixed catalyst bed. The process primarily produced a linear paraffin wax, which had use as petrochemical feedstock and also for transport fuels after further processing. This was the only process available until the 1950s/1960s when the Sasol Synthol process was developed and the process involved higher temperatures (300 to 360°C; 570 to 680°F) and medium pressures, but used a circulating fluidized bed to produce low-boiling olefins for chemicals production and naphtha components.

See also: Fischer-Tropsch Process.

Syntroleum Process

The Syntroleum process produces synthetic fuel by the Fischer-Tropsch process, which can use natural gas, coal, or biomass as feedstocks. One of the unique features of the Syntroleum process is that it uses air instead of oxygen to produce synthesis gas from natural gas in the gas-to-liquids process.

In the process, there are three major reaction steps which are (i) natural gas is first partially oxidized with air to produce synthesis gas, (ii) the synthesis gas is then reacted in a Fischer-Tropsch reactor to produce liquid hydrocarbon derivatives of various chain lengths, and (iii) the higher-boiling fraction of the products is separated and hydrocracked to transportation fuels. The liquid synthetic fuels (synfuels) produced are middle distillates consisting of naphtha, kerosene, diesel, and other hydrocarbon-based products.

See also: Fischer-Tropsch Process.

Tail Gas

Tail gas is the residual gas leaving a process, usually a Claus unit. The tail gases from the Claus units contain appreciable quantities of sulfur compounds which must be reduced before ultimate disposal of the gases to the atmosphere. The sulfur compounds in the tail gases are principally unreacted hydrogen sulfide (H_2S) and sulfur dioxide with traces of carbonyl sulfide and carbon disulfide.

The tail gas clean-up unit reduces these sulfur compounds to a level consistent with emission regulations. The Claus Unit tail gases from each train are combined, heated, and mixed with hydrogen. This mixture is then passed through a bed of cobalt-molybdenum catalyst. All of the sulfur compounds are reduced to hydrogen sulfide in this reaction.

The reactor effluent is then cooled in order to remove excess water vapor, which concentrates the hydrogen sulfide (H_2S) in the gas phase. The liquid water produced is either recycled or is fed to a sour water stripping unit. The cooled gas, now mainly nitrogen (from the Claus combustion air and the burned ammonia). Hydrogen sulfide and excess hydrogen are sweetened with very lean alkanolamine solution in a low-pressure amine absorber. The resulting sweet gas, containing only a few hundred parts per million of hydrogen sulfide, is then burned in the sulfur plant incinerator and released to the atmosphere via a tall stack. The rich alkanolamine solution is regenerated with stripping steam in a regenerator similar to the amine system regenerator. The hydrogen sulfide released is mixed with hydrogen sulfide from the main amine regenerators and is thus recycled to the Claus units as feed gas. The combination of the Claus units and the tail gas clean-up unit provides a design sulfur recovery of 99.9% w/w.

Tail gas treating is the removal of the remaining sulfur compounds from gases remaining after sulfur recovery. Tail gas from a typical Claus process, whether a conventional Claus or one of the extended versions of the process, usually contains small but varying quantities of carbonyl sulfide, carbon disulfide, hydrogen sulfide, and sulfur dioxide as well as sulfur vapor. In addition, there may be hydrogen, carbon monoxide, and carbon dioxide in the tail gas.

In order to remove the rest of the sulfur compounds from the tail gas, all of the sulfur-bearing species must first be converted to hydrogen sulfide which is then absorbed into a solvent and the clean gas vented or recycled for further processing. Examples of tail gas treating processes include the following: (i) caustic scrubbing, (ii) polyethylene glycol treatment, (iii) Selectox process, and (iv) sulfite/bisulfite tail gas treating.

See also: Claus Process, Gas Cleaning.

Tail Gas Cleaning

Tail gas cleaning (also called tail gas treating) involves the removal of the remaining sulfur compounds from gases remaining after sulfur recovery. Tail gas from a typical Claus process, whether a conventional Claus or one of the extended versions of the process, usually contains small but varying quantities of carbonyl sulfide, carbon disulfide, hydrogen sulfide, and sulfur dioxide as well as sulfur vapor. In addition, there may be hydrogen, carbon monoxide, and carbon dioxide in the tail gas. In order to remove the rest of the sulfur compounds from the tail gas, all of the sulfur-bearing species must first be converted to hydrogen sulfide which is then absorbed into a solvent and the clean gas vented or recycled for further processing.

It is necessary to develop and implement reliable and cost-effective technologies to cope with the various sales specifications and environmental requirements. In response to this trend, several new technologies are now emerging to comply with the most stringent regulations. The typical sulfur recovery efficiencies for a Claus plant is on the order of 90 to 96% w/w for a two-stage plant and 95 to 98% w/w for a three-stage plant. Most environmental agencies require the sulfur recovery efficiency to be in the range of 98.5 to 99.9+% w/w, and, as a result, the sulfur content of the Claus plant tail gas needs to be reduced further.

Moreover, a sulfur removal process must be very precise, since some gas streams may contain only a small quantity of sulfur-containing compounds that must be reduced to several orders of magnitude. Most consumers of gas require less than 4 ppm v/v in the gas – a characteristic feature of a gas stream that contains hydrogen sulfide is the presence of carbon dioxide (generally in the range of 1 to 4% v/v). In cases where the gas stream does not contain hydrogen sulfide, there may also be a relative lack of carbon dioxide.

Tail Gas Cleaning – Beavon Process

The Beavon sulfur removal process for the clean-up of Claus plant tail gas is a two-step process in which the sulfur contaminants are first catalytically hydrolyzed and/or hydrogenated to hydrogen sulfide and the hydrogen sulfide is then converted to elemental sulfur and recovered in a Stretford process unit.

In the process, which consists of two stages, the sulfur-containing compounds, such as hydrogen sulfide (H_2S), sulfur dioxide (SO_2), carbonyl sulfide (COS), and carbon disulfide (CS_2), are converted to sulfur in over 99.9% efficiency. In the first stage, the various sulfur compounds are either hydrogenated or hydrolyzed to give hydrogen sulfide, while in the second stage, the hydrogen sulfide is oxidized using the Stretford process to give good-quality elemental sulfur. This process can also be utilized in synthetic natural gas plants, natural gas processing, and other similar applications.

The Stretford process was developed during the late 1950s to remove hydrogen sulfide from town gas and was the first liquid phase, oxidation process for converting hydrogen sulfide to sulfur to gain widespread commercial acceptance. The process uses reduction-oxidation (redox) chemistry to oxidize the hydrogen sulfide to elemental sulfur, in an alkaline solution containing vanadium as an oxygen carrier.

See also: Stretford Process.

Tail Gas Cleaning – Claus Process

The Claus process is not so much a gas cleaning process but a process for the disposal of hydrogen sulfide, a toxic gas that originates in most gas streams. Burning hydrogen sulfide as a fuel gas component or as a flare gas component is precluded by safety and environmental considerations since one of the combustion products is the highly toxic sulfur dioxide (SO_2), which is also toxic. As described above, hydrogen sulfide is typically removed from gas streams by means of an olamine process after which application of heat regenerates the olamine and forms an acid gas stream. Following from this, the acid gas stream is treated to convert the hydrogen sulfide to elemental sulfur and water. The conversion process utilized in most modern refineries is the Claus process, or a variant thereof.

The Claus process involves the combustion of approximately one-third of the hydrogen sulfide to sulfur dioxide and then the reaction of the sulfur dioxide with the remaining hydrogen sulfide in the presence of a fixed bed of activated alumina, cobalt molybdenum catalyst resulting in the formation of elemental sulfur:

Different process flow configurations are in use to achieve the correct hydrogen sulfide/sulfur dioxide ratio in the conversion reactors.

In a split-flow configuration, one-third split of the acid gas stream is completely combusted, and the combustion products are then combined with the non-combusted acid gas upstream of the conversion reactors. In a once-through configuration, the acid gas stream is partially combusted by only providing sufficient oxygen in the combustion chamber to combust one-third of the acid gas.

Two or three conversion reactors may be required depending on the level of hydrogen sulfide conversion required. Each additional stage provides incrementally less conversion than the previous stage. Overall, conversion of 96 to

97% v/v of the hydrogen sulfide to elemental sulfur is achievable in a Claus process. If this is insufficient to meet air quality regulations, a Claus process tail gas treater is utilized to remove essentially the entire remaining hydrogen sulfide in the tail gas from the Claus unit. The tail gas treater may employ a proprietary solution to absorb the hydrogen sulfide followed by conversion to elemental sulfur.

See: Gas Cleaning, Tail Gas, Tail Gas Cleaning – SCOT Process.

Tail Gas Cleaning – SCOT Process

The SCOT (Shell Claus Off-gas Treating) unit is a most common type of tail gas unit and uses a hydrotreating reactor followed by amine scrubbing to recover and recycle sulfur, in the form of hydrogen, to the Claus unit.

Early SCOT units used diisopropanolamine in the Sulfinol (Sulfinol-D) solution. Methyl diethanolamine-based Sulfinol (Sulfinol-M) was used later to enhance hydrogen sulfide removal and to allow for selective rejection of carbon dioxide in the absorber. To achieve the lowest possible hydrogen sulfide content in the treated gas, the Super-SCOT configuration was introduced. In this version, the loaded Sulfinol-M solution is regenerated in two stages. The partially stripped solvent goes to the middle of the absorber, while the fully stripped solvent goes to the top of the absorber. The solvent going to the top of the absorber is cooled below that used in the conventional SCOT process.

In the process, tail gas (containing hydrogen sulfide and sulfur dioxide) is contacted with hydrogen and reduced in a hydrotreating reactor to form hydrogen sulfide and water. The catalyst is typically cobalt/molybdenum on alumina. The gas is then cooled in a water contractor. The hydrogen sulfide-containing gas enters an amine absorber which is typically in a system segregated from the other refinery amine systems. The purpose of segregation is twofold: (i) the tail gas treater frequently uses a different amine than the rest of the plant, and (ii) the tail gas is frequently cleaner than the refinery fuel gas (in regard to contaminants) and segregation of the systems reduces maintenance requirements for the SCOT unit. Amines chosen for use in the tail gas system tend to be more selective for hydrogen sulfide and are not affected by the high levels of carbon dioxide in the off-gas.

However, the SCOT process can be configured in various ways. For example, it can be integrated with the upstream acid gas removal unit if the same solvent is used in both units. Another configuration has been used to cascade the upstream gas clean-up with the SCOT unit. A hydrogen sulfide-lean acid gas from the upstream gas treating unit is sent to a SCOT process with two absorbers. In the first absorber, the hydrogen sulfide-lean acid gas is enriched, while the second absorber treats the Claus tail gas. A common stripper is used for both SCOT absorbers, and, in this latter configuration, different solvents could be used in both the upstream and the SCOT units.

A hydrotreating reactor converts sulfur dioxide in the off-gas to hydrogen sulfide that is then contacted with a Stretford solution (a mixture of a vanadium salt, anthraquinone disulfonic acid, sodium carbonate, and sodium hydroxide) in a liquid-gas absorber. The hydrogen sulfide reacts stepwise with sodium carbonate and the anthraquinone sulfonic acid to produce elemental sulfur, with vanadium serving as a catalyst. The solution proceeds to a tank where oxygen is added to regenerate the reactants. One or more froth or slurry tanks are used to skim the product sulfur from the solution, which is recirculated to the absorber. Other tail gas treating processes include: (i) caustic scrubbing, (ii) polyethylene glycol treatment, (iii) Selectox process, and (iv) a sulfite/bisulfite tail gas treating.

Tall Oil

Tall oil is an important by-product separated from the black liquor by skimming before the liquor is sent to the evaporators or after the first evaporator stage. It is a mixture of mainly acidic compounds found, like turpentine, in pine trees and obtained as a by-product of the pulp and paper industry. Tall oil is a dark, viscous, and odorous liquid that phase-separates from the used pulping liquor (alkaline black liquor) that remains after the pulping of wood chips, and contains sodium soaps of rosin and fatty acids. It is extracted at the pulp and paper mill, and undergoes the first two processing steps there.

In the first step, the black liquor from the paper making process is concentrated and left to settle. The top layer is known as “tall oil soap,” and is skimmed off. The rest is recycled for further use in paper making. In the second step, the tall oil soap is reacted with acid to form crude tall oil. The following reaction occurs:

The acids formed from this reaction, along with small quantities of other compounds of similar volatility, make up the crude tall oil. All crude tall oil produced in New Zealand is then sent to a plant in Mt. Maunganui to complete processing.

In the third step, the crude tall oil is distilled into five components with different boiling points: overhead fractions (which boil first), then fatty acids, distilled tall oil (a mixture of fatty and resin acids), resin acids (collectively known as rosin), and pitch (the residue). All of these can be used in various industries as is, but some of the rosin is also further processed on site.

The major processing feature of the distillation is that the tall oil and its products are sensitive to heat. Excessive temperature or holding at temperature for long periods of time will cause degradation and subsequent loss of product, or at least a discolored product. This is countered by the use of high vacuum for all the distillation columns and thin film wiped evaporators as the reboilers. These measures minimize the operating temperatures experienced by the fluids and the time to which they are exposed to heat. The high vacuum operation also helps in the distillation by exaggerating the relative volatility differences between the components, while also minimizing the thermal energy requirements of the process. The net result of the distillation process is the production of three main products: fatty acids, distilled tall oil, and rosin, plus some quantities of residue (pitch) and an overhead stream.

There is a reasonable market for the fatty acids and distilled tall oil but a poor market for rosin. The main value of rosin is that it can be used to manufacture rosin size and a variety of other specialty substances such as rosin oils and tackifiers. In preparation of those rosin-based products, proportions of distilled tall oil and pitch can also be utilized to maximize the saleable product recovered from the crude tall oil. Any pitch which cannot be incorporated into saleable products can be used as a fuel in the tall oil plant itself.

Tall oil itself has a variety of uses in industry. It is used as a resin in many different industries, including mining, paper manufacture, paint manufacture, and synthetic rubber manufacture. Tall oil is also used as a frothing agent in the flotation process for reclaiming low-grade copper-, lead- and zinc-bearing ores, and as a solvent or wetting agent in a variety of textile and synthetic fiber manufacturing processes. The distilled fatty acids are used in soaps, detergents, and disinfectants and as a base for lubricating greases, textile oils, cutting oils, and metal polishes. They are also used as drying agents in paint, although synthetic substances are becoming widely used. The fatty acids are unsaturated and on exposure to air undergo autoxidation and polymerization to form resin-like materials which form a tough protective coating.

Resin acids are used in rubber polymerization and compounding, as size to impart water resistance to paper (see below), and in adhesives and printing inks. Resin acids are the major component of a substance known as rosin, which is used by musicians to improve the grip of bows used for string instruments. One of the common sterols found in the unsaponifiable portion of tall oil is ergosterol, a compound which forms a number of products, including vitamin D2 (calciferol), on irradiation with ultraviolet light. If a suitable process to carry out this reaction commercially is found, then the unsaponifiable fraction of tall oil may also have a use in the future.

Tallow

Tallow is a rendered form of animal fat. More specifically, tallow is rendered mutton, beef, or other bovine fat, processed from suet. Rendered fat obtained from pigs is known as lard. From its early use in lamps, tallow is now being considered as a source of biodiesel.

Tallow is solid at room temperature, and pure tallow is a creamy-white substance. Unlike suet, tallow can be stored for extended periods without the need for refrigeration to prevent decomposition, provided it is kept in an airtight container to prevent oxidation.

The rendering process evaporates the moisture and enables the fat, known as tallow, to be separated from the high-protein solids, known as greaves. The greaves are pressed, centrifuged, or subjected to a process of solvent extraction to remove more tallow, before being ground into meat and bone meal. The viscosity of tallow can be significantly reduced by esterification, and blends of the esterified product yield a fuel with properties similar to the properties of No. 2 diesel fuel. Biodiesel from tallow has a higher cetane number than plant oil biodiesel. This means cleaner and more efficient burning in diesel engines.

Cetane numbers rate the ignition properties of diesel fuels, just as octane numbers determine the quality and value of petrol. It is a measure of ability of the fuel to ignite when it is compressed – the higher the cetane number, the more efficient the fuel.

Biodiesel has a higher cetane number than petrodiesel because of its oxygen content. The ignition quality affects engine performance, cold starting, warm up, and engine combustion roughness. A high cetane fuel also may lead to incomplete combustion and smoke if the fuel ignites too soon by not allowing enough time for the fuel to mix with air for complete combustion.

Biodiesel made from tallow has a higher cloud point than conventional diesel derived from crude oil. Because of the high levels of saturates, biodiesel from tallow tends to crystallize out at much higher temperatures than biodiesel from plant oils. In northern climates, this makes tallow biodiesel unsuitable for winter use apart from blending at low rates into conventional diesel.

Tar Removal from Gas Streams

Tar is a highly viscous liquid product (typically produced in thermal processes) that condenses in the low temperature zones of the equipment (the pyrolyzer or the gasifier), thereby interfering with the gas flow and leading to system disruption. It is, perhaps, the most undesirable product of the process, and high residual tar concentrations in the can gas prevent utilization.

Biomass is considered an important source of renewable energy needed to realize renewable energy goals and goals for the reduction of carbon dioxide emissions. Biomass gasification as a technology is recognized generally as highly desirable because of its high efficiency toward all kind of energy products. Biomass can be gasified using many different technologies ranging from high-temperature processes as high as 1,500°C (2,730°F) to low-temperature processes as low as 500°C (930°F), compared to gasifiers operated at 800 to 900°C. In many cases, the gasification process is accompanied by the formation of tar. Thus, the technical obstacle of biomass gasification technology is the effective removal of tar, which will cause the clogging of pipes and engines. In most cases, a bio-oil scrubber and the char bed are effective for tar removal.

Methods for reduction or elimination of tar can be divided into two broad groups: (i) in situ tar reduction, also called primary tar reduction, which focuses on reducing or avoiding tar formation in the reactor, and (ii) post-gasification tar reduction, also called secondary tar reduction, which strips the tar from the product gas. A combination of in situ and post-gasification tar reductions can prove to be more effective than either of the single stages alone. The two basic post-gasification methods are physical removal and cracking (catalytic or thermal).

See also: Gas Cleaning.

Tar Removal from Gas Streams – Physical Methods

In a process for the physical removal of tar, the tar is treated tar as dust particles or mist and the tar is condensed before separation. Physical tar removal can be accomplished by cyclones, barrier filters, wet electrostatic precipitators (ESPs), or wet scrubbers. The selection of the equipment application depends on the load concentrations of particulate matter (PM) and tar, particle size distribution, and particulate tolerance of downstream users.

Cyclone collectors are the most common of the inertial collector class and are effective in removing coarser fractions of particulate matter and operate by contacting the particles in the gas stream with a liquid. In principle, the particles are incorporated in a liquid bath or in liquid particles which are much larger and therefore more easily collected. In the process, the particle-laden gas stream enters an upper cylindrical section tangentially and proceeds

downward through a conical section. Particles migrate by centrifugal force generated by providing a path for the carrier gas to be subjected to a vortex-like spin. The particles are forced to the wall and are removed through a seal at the apex of the inverted cone. A reverse-direction vortex moves upward through the cyclone and discharges through a top center opening. Cyclones are often used as primary collectors because of their relatively low efficiency (50 to 90% is usual). Cyclones may not be efficient when removing small tar droplets, and barrier filters are porous material which can capture a certain amount of tar when the product gas passes through the filters. As an aid, catalyst grains can be integrated as a fixed bed inside the filter to promote the simultaneous removal of particulate matter and tar.

Fabric filters are typically designed with non-disposable filter bags. As the gaseous (dust-containing) emissions flow through the filter media (typically cotton, polypropylene, fiberglass, or Teflon), particulate matter is collected on the bag surface as a dust cake. Fabric filters operate with collection efficiencies up to 99.9% although other advantages are evident, but there are several issues that arise during use of such equipment.

Wet scrubbers are devices in which a countercurrent spray liquid is used to remove particles from an air stream. Device configurations include plate scrubbers, packed bed scrubbers, orifice scrubbers, venturi scrubbers, and spray towers, individually or in various combinations. Wet scrubbers can achieve high collection efficiencies at the expense of prohibitive pressure drops. The *foam scrubber* is a modification of a wet scrubber in which the particle-laden gas is passed through a foam generator, where the gas and particles are enclosed by small bubbles of foam.

Electrostatic precipitators operate on the principle of imparting an electric charge to particles in the incoming air stream, which are then collected on an oppositely charged plate across a high-voltage field. Particles of high resistivity create the most difficulty in collection. Conditioning agents such as sulfur trioxide (SO_3) have been used to lower resistivity. Important parameters include design of electrodes, spacing of collection plates, minimization of air channeling, and collection-electrode rapping techniques (used to dislodge particles). Techniques under study include the use of high-voltage pulse energy to enhance particle charging, electron-beam ionization, and wide plate spacing. Electrical precipitators are capable of efficiencies >99% under optimum conditions, but performance is still difficult to predict in new situations. Wet electrostatic precipitator units have a high collection efficiency (on the order of 90%) over the entire range of particle size down to 0.5 μm with a very low-pressure drop. Wet scrubbers can achieve a high collection efficiency (also on the order of 90%).

Other methods include use of high-energy input *venturi scrubbers* or electrostatic scrubbers where particles or water droplets are charged, and flux force/condensation scrubbers where a hot humid gas is contacted with cooled liquid or where steam is injected into saturated gas. In the latter scrubber, the movement of water vapor toward the cold water surface carries the particles with it (*diffusiophoresis*), while the condensation of water vapor on the particles causes the particle size to increase, thus facilitating collection of fine particles.

See also: Gas Cleaning.

Tar Removal from Gas Streams – Thermal Methods

Cracking methods are more advantageous in terms of recovering the energy content in the tar by converting the high-molecular-weight constituents of the tar into lower-molecular-weight (gaseous) products such as hydrocarbon derivatives and hydrogen at high temperature (up to 1,200°C, 2,190°F) or catalytic reactions (up to 800°C, 1,470°F). Catalytic cracking is commercially used in many refineries plants and has been demonstrated to be one of the most effective processes for the conversion of high-molecular-weight products (such as crude oil residua, heavy oil, extra heavy oil, and tar sand bitumen) into gases and lower-molecular-weight distillable and liquids.

Non-metallic catalysts such as dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$), calcite (CaCO_3), zeolite, and metallic catalysts such as nickel-based catalysts, nickel/molybdenum-based catalysts, nickel/cobalt-based catalysts, molybdenum-based catalysts, platinum-based catalysts, and ruthenium-based catalysts Mo, NiO, Pt, and Ru have been applied to various tar conversion processes.

Tar removal can also be achieved by catalytic reforming which has the advantage of keeping the carbon contained in the tars available for further conversion to fuel. Another option to reduce the tar content of the synthesis gas is the use of catalytic bed material in the gasification reactor. Olivine sand has been shown to effectively reduce the tar content in a gas stream from steam gasification.

See also: Gas Cleaning.

Tar Sand

Tar sand (also referred to as oil sand) is a combination of clay, sand, water, and bitumen, a heavy black viscous material that resembles petroleum residua. Tar sand can be mined and processed to extract the oil-rich bitumen, which is then refined into oil. The bitumen in tar sand cannot be pumped from the ground in its natural state. Instead, tar sand deposits are mined, usually using strip mining or open pit techniques, or the oil is extracted by underground heating with additional upgrading.

Tar sand have been defined in the United States (FE-76-4) as:

...the several rock types that contain an extremely viscous hydrocarbon which is not recoverable in its natural state by conventional oil well production methods including currently used enhanced recovery techniques. The hydrocarbon-bearing rocks are variously known as bitumen-rocks oil, impregnated rocks, oil sands, and rock asphalt.

By inference, heavy oil can be recovered in its natural state by enhanced oil recovery techniques while conventional crude oil can be recovered in its natural state by secondary and primary recovery techniques. Also by inference, black oil does not reliably fit into this definition.

To recover bitumen from tar sand recovery processes involves extraction and separation systems to separate the bitumen from the clay, sand, and water that make up the tar sand. Bitumen also requires additional upgrading before it can be refined. Because it is so viscous (thick), it also requires dilution with lighter hydrocarbons to make it transportable by pipelines.

Resources

Much of the potential oil of the world (more than 2 trillion barrels, 2×10^{12} barrels) is in the form of tar sand, although it is not all recoverable. While tar sand deposits are found in many places worldwide, the largest deposits in the world are found in Canada (Alberta) and Venezuela, and much of the rest is found in various countries in the Middle East. In the United States, tar sand resources are primarily concentrated in Eastern Utah, mostly on public lands.

The Industry

Currently, synthetic crude oil is not produced from tar sand on a significant commercial level in the United States; in fact, only Canada has a large-scale commercial tar sand industry, though a small amount of oil from tar sand is produced commercially in Venezuela. The Canadian tar sand industry is centered in Alberta, and more than one million barrels of synthetic oil are produced from these resources per day. Currently, synthetic crude oil from tar sand deposits represents approximately 40% of Canada's oil production, and the output is expanding rapidly. Approximately 20% of U.S. crude oil and products come from Canada, and a substantial portion of this amount comes from tar sand. The bitumen from tar sand is extracted both by mining and *in situ* recovery methods.

Bitumen Extraction and Processing

Thermal recovery methods have found most use when tar sand bitumen has an extremely high viscosity under reservoir conditions. For example, tar sand bitumen is highly viscous, with a viscosity ranging from a thousand centipoises to a million centipoises or more at the reservoir conditions. In addition, oil viscosity is also a function of temperature and API gravity.

Thermal enhanced oil recovery processes (i.e., cyclic steam injection, steam flooding, and in situ combustion) add heat to the reservoir to reduce oil viscosity and/or to vaporize the oil. In both instances, the oil is made more mobile so that it can be more effectively driven to producing wells. In addition to adding heat, these processes provide a driving force (pressure) to move oil to producing wells. In situ combustion may make a comeback with a new concept. THAI (toe-to-heel air injection) is based on the geometry of horizontal wells that may solve the problems that have plagued conventional in situ combustion.

In situ conversion, or underground refining, is a promising new technology to tap the extensive reservoirs of heavy oil and deposits of bitumen. The new technology (Gregoli and Rimmer, 2000; Gregoli et al., 2000) features the injection of high-temperature, high-quality steam and hot hydrogen are into a formation containing heavy hydrocarbons to initiate conversion of the heavy hydrocarbons into lighter hydrocarbons. In effect, the heavy hydrocarbons

undergo partial underground refining that converts them into a synthetic crude oil (or *syncrude*). The heavier portion of the syncrude is treated to provide the fuel and hydrogen required by the process, and the lighter portion is marketed as a conventional crude oil.

Thus, below ground, superheated steam and hot hydrogen are injected into a tar sand formation, which simultaneously produces the bitumen and converts it *in situ* (i.e., within the formation) into syncrude. Above ground, the heavier fraction of the syncrude is separated and treated on-site to produce the fuel and hydrogen required by the process, while the lighter fraction is sent to a conventional refinery to be made into petroleum products.

The potential advantages of an *in situ* process for tar sand bitumen include (i) leaving the carbon forming precursors in the ground, (ii) leaving the heavy metals in the ground, (iii) reducing the sand handling, and (iv) bringing a partially upgraded product to the surface. The extent of the upgrading can, hopefully, be adjusted by adjusting the exposure of the bitumen of heavy oil to the underground thermal effects.

In the *modified in situ extraction* processes, combinations of *in situ* and mining techniques are used to access the reservoir. A portion of the reservoir rock must be removed to enable application of the *in situ* extraction technology. The most common method is to enter the reservoir through a large-diameter vertical shaft, excavate horizontal drifts from the bottom of the shaft, and drill injection and production wells horizontally from the drifts. Thermal extraction processes are then applied through the wells. When the horizontal wells are drilled at or near the base of the tar sand reservoir, the injected heat rises from the injection wells through the reservoir, and drainage of produced fluids to the production wells is assisted by gravity.

Generally, tar sand bitumen recovery requires a higher degree of thermal stimulation because bitumen, in its immobile state, is extremely difficult to move to a production well. Extreme processes are required, usually in the form of a degree of thermal conversion that produces free-flowing product oil that will flow to the well and reduce the resistance of the bitumen to flow.

The mining method of bitumen recovery has received considerable attention since it was chosen as the technique of preference for the only two commercial bitumen recovery plants in operation in North America. *In situ* processes have been tested many times in the United States, Canada, and other parts of the world and are ready for commercialization. There are also conceptual schemes that are a combination of both mining (above-ground recovery) and *in situ* (non-mining recovery) methods.

Engineering a successful oil mining project must address a number of items because there must be sufficient recoverable resources, the project must be conducted safely, and the project should be engineered to maximize recovery within economic limits. The use of a reliable screening technique is necessary to locate viable candidates. Once the candidate is defined, this should be followed by an exhaustive literature search covering the local geology, drilling, production, completion, and secondary and tertiary recovery operations.

The reservoir properties, which can affect the efficiency of bitumen production by mining technology, can be grouped into three classes: (i) the primary properties, which are the properties that have an influence on the fluid flow and fluid storage properties and include rock and fluid properties, such as porosity, permeability, wettability, crude oil viscosity, and pour point, (ii) the secondary properties, which are the properties that significantly influence the primary properties, including pore size distribution, clay type, and content, and (iii) the tertiary properties, which are the properties that mainly influence oil production operation (fracture breakdown pressure, hardness, and thermal properties) and the mining operations (e.g., temperature, subsidence potential, and fault distribution).

There are also important rock mechanical parameters of the formation in which a tunnel is to be mined and from where all oil mining operations will be conducted. These properties are mostly related to the mining aspects of the operations, and not all are of equal importance in their influence on the mining technology. Their relative importance also depends on the individual reservoir.

Many of the candidate reservoirs for application of improved oil mining are those with high oil saturation resulting from the adverse effects of reservoir heterogeneity. Faulting, fracturing, and barriers to fluid flow are features that cause production of shallow reservoirs by conventional methods to be inefficient. Production of heterogeneous reservoirs by underground oil production methods requires consideration of the manner in which fractures alter the flow of fluids.

After mining, the tar sand is transported to an extraction plant, where a hot water process separates the bitumen from sand, water, and minerals. The separation takes place in separation cells. Hot water is added to the sand, and the resulting slurry is piped to the extraction plant where it is agitated.

The hot water process is, to date, the only successful commercial process to be applied to bitumen recovery from mined tar sands in North America. The process utilizes the linear and the nonlinear variation of bitumen density and water density, respectively, with temperature so that the bitumen that is heavier than water at room temperature becomes lighter than water at 80°C (180°F). Surface-active materials in the tar sand also contribute to the process. The essentials of the hot-water process involve a conditioning, separation, and scavenging.

Thus, in the hot water extraction process, the tar sand feed is introduced into a *conditioning* drum. In this step, the oil sand is heated, mixed with water, and agglomeration of the oil particles begins. The conditioning is carried out in a slowly rotating drum that contains a steam-sparging system for temperature control as well as mixing devices to assist in lump size reduction and a size ejector at the outlet end. The oil sand lumps are reduced in size by ablation and mixing action. The conditioned *pulp* has the following characteristics: (i) solids 60 to 85%; and (ii) pH 7.5 to 8.5.

In the conditioning step, also referred to as mixing or pulping, tar-sand feed is heated and mixed with water to form a pulp of 60% by weight to 85% by weight solids at 80°C to 90°C (175°F to 196°F). First, the lumps of tar sand as-mined are reduced in size by ablation, i.e., successive layers of lump are warmed and sloughed off revealing cooler layers. The conditioned pulp is screened through a double-layer vibrating screen. Water is then added to the screened material (to achieve more beneficial pumping conditions), and the pulp enters the separation cell through a central feed well and distributor. The bulk of the sand settles in the cell and is removed from the bottom as tailing, but the majority of the bitumen floats to the surface and is removed as froth. A middlings stream (mostly of water with suspended fines and some bitumen) is withdrawn from approximately midway up the side of the cell wall. Part of the middlings is recycled to dilute the conditioning drum effluent for pumping. Clays do not settle readily and generally accumulate in the middlings layer. High concentrations of clays increase the viscosity and can prevent normal operation in the separation cell. Thus, it is necessary to withdraw a drag stream to act as a purge; this is usually done at high clay concentrations but may not be as essential with a low-clay oil sand charge.

Both mining and processing of tar sand involve a variety of environmental impacts, such as global warming and greenhouse gas emissions, disturbance of mined land, and impacts on wildlife and air and water quality. The development of a commercial tar sand industry in the United States would also have significant social and economic impacts on local communities. Of special concern in the relatively arid western United States is the large amount of water required for tar sand processing; currently, tar sand extraction and processing require several barrels of water for each barrel of oil produced, though some of the water can be recycled.

A variant of tar sand bitumen – referred to as extra heavy crude oil and which has mobility because of the high temperature of the deposit – is found predominantly in Venezuela. In relation to the bitumen in the Alberta tar sand deposits, approximately 15 to 20% v/v of the bitumen is recoverable, which amounts to approximately 75% v/v of the crude oil reserves in North America. Furthermore, it is only recently that the deposits of tar sand have been recognized as viable energy sources, and there have been changes in the way the world views oil reserves, and tar sand reserves have come to be included in the tally of global crude oil and heavy crude oil reserves.

In spite of the high estimations of the reserves of bitumen, the two conditions of vital concern for the economic development of tar-sand deposits are the concentration of the resource, or the percent bitumen saturation, and its accessibility, usually measured by the overburden thickness. Recovery methods are based either on mining combined with some further processing or operation on the oil sands *in situ*. The mining methods are applicable to shallow deposits, characterized by an overburden ratio (i.e., overburden depth to thickness of tar-sand deposit) that is deposit specific. For example, indications are that for the Athabasca deposit, no more than 15 to 20% v/v of the in-place deposit is available within current concepts of the economics and technology of open-pit mining and advanced non-mining recovery techniques.

TEA

Ethanolamine derivatives became available commercially in the early 1930s; they assumed steadily growing commercial importance as intermediates after 1945, because of the large-scale production of ethylene oxide. Since the mid-1970s, economical production of very pure, colorless ethanolamines has been possible. Ethanolamine derivatives are produced on an industrial scale exclusively by reaction of ethylene oxide and excess ammonia. This reaction takes place slowly, but is accelerated by water. An anhydrous procedure uses a fixed-bed ion-exchange resin catalyst.

Acid gas removal is an important process in various branches of the hydrocarbon processing industry, primarily in natural gas processing and refining. Acid gas removal is also an essential part of other processes, such as coal gasification where carbon dioxide, hydrogen sulfide, carbonyl sulfide, mercaptan derivatives, and other contaminants need to be removed. Acid gas is defined as gas containing significant amounts of contaminants, such as hydrogen sulfide (H_2S), carbon dioxide (CO_2), and other acidic gases. Sour gas is gas contaminated with hydrogen sulfide, and, thus, gas sweetening refers to hydrogen sulfide removal, because it improves the odor of the gas being processed, while the term acid gas removal refers to the removal of both hydrogen sulfide and carbon dioxide. Acid gases need to be removed in order to comply with sales gas quality regulations. One such treatment for acid gas removal involves the use of ethanolamine derivatives, especially triethanolamine (TEA).

Triethanolamine (TEA) is an organic chemical compound which is both a tertiary amine and a tri-alcohol (i.e., the molecule contains three hydroxyl groups).

Like other amines, triethanolamine acts as a weak base due to the lone pair of electrons located on the nitrogen atom. See also: Gas Cleaning, Oamine Processes.

Tertiary Biomass Feedstocks

Tertiary biomass feedstock includes post-consumer residues and wastes, such as fats, greases, oils, construction and demolition wood debris, other waste wood from the urban environments, as well as packaging wastes, municipal solid wastes, and landfill gases. A category other wood waste from the urban environment includes trimmings from urban trees, which technically fits the definition of primary biomass. However, because this material is normally handled as a waste stream along with other post-consumer wastes from urban environments (and included in those statistics), it makes the most sense to consider it to be part of the tertiary biomass stream.

Tertiary biomass includes post-consumer residues and wastes, such as fats, greases, oils, construction and demolition wood debris, other waste wood from the urban environments, as well as packaging wastes, municipal solid wastes, and landfill gases.

The category “other wood waste from the urban environment” could include trimmings from urban trees, which technically fits the definition of primary biomass. However, because this material is normally handled as a waste stream along with other post-consumer wastes from urban environments (and included in those statistics), it makes the most sense to consider it to be part of the tertiary biomass stream.

The proper categorization of fats and greases may be debatable since those are by-products of the reduction of animal biomass into component parts. However, since animals can be considered to be a type of biomass processing factory and since most fats and greases, and some oils, are not available for bioenergy use until after they become a post-consumer waste stream, it seems appropriate for them to be included in the tertiary biomass category. Vegetable oils derived from processing of plant components and used directly for bioenergy (e.g., soybean oil used in biodiesel) would be a secondary biomass resource, though the amounts being used for bioenergy are most likely to be tracked together with fats, greases, and waste oils.

Texaco Gasification Process

The Texaco process is used to gasify coal under high pressure in an entrained bed by the injection of oxygen (or air) and steam with concurrent gas/solid flow. The process uses the entrained bed technology and is basically used to manufacture synthesis gas.

In the process, the feedstock, together with the feedstock carbon slurry recovered in the carbon recovery section, is pressurized to a given pressure, mixed with high-pressure steam, and then blown into the gas generator through the burner together with oxygen.

The gasification reaction is a partial oxidation of hydrocarbons to carbon monoxide and hydrogen:

The gasification reaction is instantly completed, thus producing gas mainly consisting of H_2 and CO ($\text{H}_2 + \text{CO} = >90\%$). The high-temperature gas leaving the reaction chamber of the gas generator enters the quenching chamber linked to the bottom of the gas generator and is quenched to 200 to 260°C (390 to 500°F) with water.

The coal is crushed in a two-stage system (the second step performed under an inert atmosphere) and is then mixed with water or oil to form a pumpable slurry which is pumped under pressure into the gasifier vessel (a refractory-lined chamber inside a pressure vessel). In this unit, the slurry reacts with either air or oxygen at high temperature; the product gas from the reactor contains primarily carbon monoxide and hydrogen, but may contain appreciable quantities of nitrogen if the reactor is air-blown.

Oils or tars are not usually produced by the process, and methane is the only hydrocarbon gas generated.

The product gases and molten slag produced in the reaction zone pass downward through a water spray chamber and a slag quench bath, and the cooled gas and slag are then removed for further treatment.

The gas leaving the quench unit, once it is separated from the slag, is treated to remove the carbon fines and ash. The gas is then subsequently recycled to the slurry preparation system and treated for acid gas removal; elemental sulfur is recovered from the hydrogen sulfide-rich stream.

The partial oxidation unit is also used to gasify crude oil residua and can be adjusted so that the effluent gas stream has little, or no, hydrocarbon content.

Texaco Gasifier

Gasification has been used commercially around the world for more than a century by the chemical, refining, and fertilizer industries and for more than 35 years by the electric-power industry.

Gasification technologies can also be used to convert combined feedstocks, such as coal and biomass, in the same gasifier at the same time. Thermochemical conversion would use nonfood biomass feedstocks – such as lignin, cellulose, and plastic wastes – and thus would not raise issues of competition between the markets for fuel and food.

The Texaco gasifier is an entrained-flow, high-pressure, and high-temperature slagging system that is based on a commercially proven crude oil gasifier. Although developed for coal gasification, this type of (entrained-flow) gasifier lends itself to the gasification of dry lignocellulosic biomass. The process is compatible with biomass feedstocks from agriculture, mainly straw, which have a higher ash, potassium, and chlorine content and a lower ash softening point than wood.

The first step is a fast pyrolysis at atmospheric pressure, which produces much condensate and only little char and gas. Pyrolysis condensate and pulverized pyrolysis char are then mixed to a slurry, containing up to 90% of the initial biomass energy. In contrast to the loose-packed original biomass, the dense slurries are easily pumped and stored in tanks. From a number of regional pyrolysis plants, the slurries can be transported by rail to a large central gasification facility. The slurries are pumped into a slagging entrained flow gasifier and are atomized and converted to syngas at high operating temperatures and pressures, above the operating pressure of a downstream synthesis plant.

At high pressures, alternative operation of pressure locks with a low-bulk density biomass will become too expensive. High gasification temperatures and pressures help to produce a tar-free syngas, simplify downstream gas cleaning steps, and obviate intermediate compression before synthesis. To achieve high process efficiency, the utilization of chemical energy in synthesis products like methanol must be complemented by the use of sensible heat for electric power generation.

The economy of scale can make possible an efficient but more complex gasification and syngas utilization technology, to produce the most valuable products.

See also: Gasification.

Thermal Conversion

Thermal conversion (sometimes referred to as thermochemical conversion) involves either the gasification of biomass or coal followed by synthesis to liquid fuels (indirect liquefaction) or the direct conversion of coal to liquid fuels (direct liquefaction) with high-pressure hydrogen (H_2).

Those thermochemical conversion processes are considered to be ready for deployment between now and 2020. Because of its chemical complexity, biomass can also be converted to liquid fuels by pyrolysis or liquefaction, but these routes are not as well developed.

Thermal processes include pyrolysis, gasification, and combustion. Pyrolysis normally proceeds at temperatures below approximately 600°C (1,110°F), while in gasification processes, temperatures range from 800 to 1,100°C (1,470 to 2,110°F) or even higher in slagging systems, and combustion temperatures are 1,500°C (2,730°F) or more.

Pyrolysis occurs in the absence of oxygen, and other chemical reactants are usually not used. The products of pyrolysis are gases, liquids, and a carbonaceous char, in relative amounts dependent on the properties of the biomass, the rate of heating, and the final temperature attained. Slow pyrolysis produces mainly char, while with rapid pyrolysis, the liquid and gaseous yields are increased. Pyrolysis in a hydrogen atmosphere (hydropyrolysis) also increases the gaseous yield relative to char, and generally produces a high quantity and quality of liquid product.

In the case of gasification, one or more reactants, such as oxygen, steam, or hydrogen, are introduced into the system. These chemical reactants combine with solid carbon at the higher gasification temperatures, so increasing the gas yield while consuming char. The amount of char by-product remaining on gasification is in fact essentially zero with biomass materials, while the small quantity of tars and oils evolved may be recycled to extinction. The introduced reactants also enter into gas phase reactions which, together with the shift in equilibrium and the change in relative reaction rates at the higher temperatures, results in a significantly better-quality gas than that obtained on pyrolysis. Important distinctions between pyrolysis and gasification are therefore the improved gas yield and the elimination of solid and liquid by-products. These advantages are gained at the cost of a more complex process.

Gasification results in only a partial oxidation of the carbon constituent. Much of the calorific value of the original fuel leaves the gasifier in the form of chemical energy in carbon monoxide, methane, and hydrogen. In combustion, air containing sufficient oxygen to completely oxidize the hydrocarbon is used. The resulting gas (flue gas) is essentially all carbon dioxide, water vapor, and diluent nitrogen, and has no calorific value. The energy of the original fuel leaves the system as sensible heat that can be used for steam raising and, if required, electricity generation. Combustion offers a practical means for recovering the energy in biomass materials, using currently available technology. Further, it is well suited to small-scale utilization, a factor that seems to be of importance on account of the dispersed nature of the resource.

The properties of biomass that have a significant bearing on its thermal conversion are its relatively high moisture, oxygen, hydrogen, and volatile matter content, and low energy density. The high oxygen and hydrogen contents account for the high proportion of volatile matter and consequently high yields of gases and liquids on pyrolysis. The advantages of the high H/C ratio associated with biomass are not reflected in the products to the extent that might be expected. In fact, pyrolysis gases can be deficient in pure hydrogen and pyrolysis liquids are highly oxygenated, viscous tars.

An additional and significant source of water vapor in biomass gases is the high moisture content of the source materials. In countercurrent flow schemes such as the Lurgi moving bed gasifier, this water is evolved in the relatively low temperature drying and pyrolysis zones and does not partake in gas phase or carbon-steam gasification reactions. On the other hand, in fluidized bed systems, the moisture is evolved in the high-temperature well-mixed reaction zone and therefore does participate in the reactions. If the system is directly heated and air blown, the additional heat required to evaporate the water will result in more nitrogen being introduced, and more carbon dioxide being produced, so reducing the calorific value of the product gas. As the gas from air-blown processes is, in any case, a low-CV product, this factor is probably of little consequence other than with very wet feedstock. In oxygen-blown

systems, however, the additional pure oxygen required and higher carbon dioxide content of the medium-CV off gas may be of sufficient impact to dictate some degree of drying as a pretreatment.

Apart from drying, additional beneficiation may be undertaken to yield a resource of higher energy density. These operations will normally be undertaken at the source, so transport and subsequent storage costs may be reduced as well. Beneficiation steps include size reduction and densification. Waste heat, if available, may be used for drying, while size reduction and compression to form pellets or briquettes is estimated to require less than 2% of the energy in the dry biomass. Nevertheless, these operations are time consuming, and can be either labor or capital intensive.

Some advantages of biomass over conventional fossil fuels, not so far discussed, are their low-sulfur content and their relatively highly reactive chars. In addition, biomass materials do not cake and can therefore be easily handled in both fluidized and moving bed reactors. Finally, catalyst poisons are not present in biomass in significant concentrations. This can be important for the initial thermal processing as well as for subsequent upgrading operations.

The most suitable biomass resources for thermal conversion are wood and the organic portion of municipal solid waste. Crop residues and grasses are of intermediate value, although thermal conversion might prove more effective than fermentation. If the versatility of a liquid fuel is desired, gasification may be combined with methanol or Fischer-Tropsch synthesis.

Very wet resources such as aquatic biomass and animal wastes are not suited to thermal conversion, and are best reserved for anaerobic digestion.

Thermal Cracking

Thermal cracking is a chemical process by which organic molecules are decomposed into lower-molecular-weight products. Thermal cracking can take place in the presence of a catalyst (catalytic cracking) or in the presence of hydrogen or a hydrogen-rich gas (hydrocracking).

The thermal cracking of carbonaceous feedstocks does not require the addition of a catalyst. This approach is the oldest technology available for feedstock conversion, and the severity of thermal processing determines the conversion and the product characteristics. As the temperature and residence time are increased, the primary products undergo further reaction to produce various secondary products, and so on, with the ultimate products (coke and methane) being formed at extreme temperatures of approximately 1,000°C (1,830°F).

Typically, carbonaceous feedstocks contain many thousands of different compounds, and this broad range in molecular weights results in boiling points that range from -160°C (-288°F) to temperatures in excess of on the order of 1,200°C (2,190°F). The higher-molecular-weight constituents of the feedstock are converted by thermal methods to lower-molecular-weight products that are refined and prepared for the market. Thus, understanding the thermal chemistry of any feedstock not only allows an explanation of the means by which products can be formed from the feedstock but also offers an option of predictability.

See: Thermal Conversion, Thermal Decomposition.

Thermal Decomposition

The thermal decomposition of carbonaceous feedstocks on a commercial scale is an old art and is often more commonly referred to as carbonization. In the process, a mix of solid, liquid, and gaseous products is usually achieved by the use of temperatures up to 1,500°C (2,730°F). The process may also be referred to as destructive distillation and has been applied to a whole range of organic materials, but more particularly to natural products such as wood, sugar, and vegetable matter to produce charcoal.

However, carbonization is a process for the production of a carbonaceous residue (coke) by the thermal decomposition (with simultaneous removal of distillate) of organic substances. The process, which is also referred to as destructive distillation, has been applied to a whole range of organic (carbon-containing) materials, particularly natural products such as wood, sugar, and vegetable matter to produce charcoal. In this present context, the

carbonaceous residue from the thermal decomposition of coal is usually referred to as coke (which is physically dissimilar from charcoal) and has the more familiar honeycomb-type structure. Thus, thermal decomposition is essentially a process for the production of volatile products as well as a carbonaceous residue by heating the feedstock (with the simultaneous removal of distillate) of organic substances.

$$[C]_{\text{organic}} = [C]_{\text{coke/char/carbon}} + \text{liquids} + \text{gases}$$

The thermal decomposition process is a complex sequence of events which can be described in terms of several important physicochemical changes, such as the tendency of the feedstock (in some cases) coal to soften and flow. In fact, some coals become quite fluid at temperatures of the order of 400 to 500°C (750 to 940°F), and there is a considerable variation in the degree of maximum plasticity, the temperature of maximum plasticity, as well as the plasticity temperature range for various coals. Indeed, significant changes also occur in the structure of the char during the various stages of devolatilization.

See also: Carbonization, Thermal Conversion.

Thermochemical Platform

The thermochemical platform typically uses a combination of pyrolysis, gasification, and catalysis to transform wood into syngas – the gaseous constituents of wood – and then into fuels or chemicals. Syngas production through pyrolysis is accompanied by the generation of char, which can then be gasified to provide process heat and energy for the thermochemical platform. A variety of commercial-scale processes exist to transform fossil fuels such as coal or natural gas into liquid fuels, including Fischer-Tropsch fuels. However, the use of biomass instead of fossil fuels changes the composition of syngas, creating a more heterogeneous intermediate product and increasing the difficulty in downstream catalysis. A range of technical problems must be overcome before biomass becomes a commercially viable substitute for fossil feedstocks in second-generation biofuel production. However, the elements of the thermochemical platform are highly suitable for bioenergy production.

This platform uses thermochemical processes to gasify wood, producing synthesis gases (sometimes called producer gases). This platform combines process elements of pretreatment, pyrolysis, gasification, clean-up, and conditioning to generate a mixture of hydrogen, carbon monoxide, carbon dioxide, and other gases. The products of this platform may be viewed as intermediate products, which can then be assembled into chemical building blocks and eventually end products.

In the thermochemical platform, the only pretreatment required involves drying, grinding, and screening the material in order to create a substrate that can easily be fed into the reaction chamber. The technology required for this stage is already available on a commercial basis, and is often associated with primary or secondary wood processing, or agricultural residue collection and distribution.

In the primary processing stage, the volatile components of biomass are subjected to pyrolysis or combustion in the absence of oxygen, at temperatures ranging from 450 to 600°C (840 to 1,110°F). Depending on how fast the pyrolysis stage is carried out, a variety of products can be achieved. If pyrolysis is carried out quickly (fast pyrolysis), a combination of vapors, condensable vapors, and char is produced. The condensation of these products creates a bio-oil which, under ideal conditions can make up 60 to 75% w/w of the original fuel mass, and can be used as feedstock for value-added chemical products, or possibly as a biofuel. If the pyrolysis is carried out at a slower rate (slow pyrolysis), the vapors that are formed are less likely to condense into bio-oil. The vapors themselves consist of carbon monoxide, hydrogen, methane, carbon dioxide, and water, as well as volatile tars.

Slow pyrolysis, like fast pyrolysis, leaves behind a solid residue of char (or charcoal), which comprises approximately 10 to 25% w/w of the original fuel mass, and processing this material requires a second gasification stage.

If the pyrolysis is carried out at the higher temperature range (550 to 600°C; 1,020 to 1,110°F), a vapor is formed which consists of carbon monoxide, hydrogen, methane, volatile tars, carbon dioxide, and water. High temperature pyrolysis leaves behind a solid residue of char (or charcoal), which makes up approximately 10 to 25% w/w of the

original fuel mass. This material can then be gasified at temperatures of 700 to 1,200°C (1,290 to 2,190°F), at which temperatures the char reacts with oxygen in order to produce carbon monoxide, or the char can be used as fuel to drive the pyrolysis process. All gaseous products from pyrolysis and gasification are generally referred to as synthesis gases (or syngas).

After the production of syngas, a number of pathways may be followed to create second-generation biofuels or other chemical, heat, or energy products. It is possible to create one potential biofuel from the thermochemical platform without a catalysis stage.

Bio-oil has been advocated as a substitute for bunker-grade heating oil, and is approved for use in district heating utility boilers in Sweden and has been mixed with coal in a co-firing facility in the United States successfully. Other biofuels may be generated by applying a catalysis stage. Methanol is one potential biofuel that can be generated through catalysis. Currently, the majority of methanol produced is being derived from natural gas. Methanol has a high octane number (129) but relatively low energy compared to gasoline (91 to 98 octane).

Conceivably, methane could be used in higher or as a stand-alone fuel, although this would require significant infrastructure changes as well as modifications to conventional engines. Because methanol has a favorable hydrogen/carbon ratio (4:1), it is often touted as a potential hydrogen source for future transportation systems.

Another potential biofuel that can be produced through the thermochemical platform is Fischer-Tropsch diesel (or biosynthetic diesel). This fuel was first discovered in 1923 and is commercially based on syngas made from coal, although the process could be applied to biomass-derived syngas.

Another potential catalytic conversion of biomass-based syngas is to higher alcohols, including ethanol. Ethanol and other higher alcohols form as by-products of both Fischer-Tropsch and methanol synthesis, and modified catalysts have been shown to provide better yields. The thermochemical platform provides the opportunity for a number of additional co-products, as well as energy in the form of heat or electricity and biofuels. Each syngas component (i.e., CO, CO₂, CH₄, H₂) may be recovered, separated, and utilized.

A variety of commercial-scale processes exist to transform fossil fuels such as coal or natural gas into liquid fuels, including Fischer-Tropsch fuels. However, the use of biomass instead of fossil fuels changes the composition of synthesis gas, creating a more heterogeneous intermediate product and increasing the difficulty in downstream catalysis. A range of technical problems must be overcome before biomass becomes a commercially viable substitute for fossil feedstocks in second-generation biofuel production, but, in general, it is felt that elements of the thermochemical platform are highly suitable for bioenergy production.

Thermosphere

The outermost layer of the atmosphere, the thermosphere, blocks a variety of harmful cosmic radiation including X-rays, gamma rays, and some ultraviolet radiation. Temperatures in the upper thermosphere may reach 1,500°C (2,730°F), but the number of atoms is so small at this altitude that heat energy is actually low. Isolated gas molecules in the thermosphere are broken into ions as solar radiation strips electrons from oxygen and nitrogen molecules. These ionized gases make up the ionosphere, from 50 to 250 miles. Visible effects (auroras, such as the Aurora Borealis in northern latitudes and the Aurora Australis in southern latitudes) occur when electrons and protons from the sun interact in the ionosphere.

At these high altitudes, the residual atmospheric gases sort into strata according to molecular properties, such as density. The temperature in the thermosphere increases with altitude due to absorption of highly energy solar radiation, and, in fact, the temperature is highly dependent on solar activity, and can rise to 1,700°C (3,100°F) or even higher. Radiation causes the atmosphere particles in this layer to become electrically charged particles, thereby enabling radio waves to be refracted and thus be received beyond the horizon.

The dynamics of the thermosphere are dominated by atmospheric tides, which are driven predominantly by diurnal heating. Atmospheric waves dissipate above this level because of collisions between the neutral gas and the ionospheric plasma.

Thiolex/Regen Process

The Thiolex/Regen process is used to extract hydrogen sulfide, carbonyl sulfide, and mercaptans from gases and high liquid streams, including gasoline, with caustic using fiber-film contactor technology.

The caustic phase flows along the fiber-film contactor fibers, which is continuously renewed, as the wet fibers are preferentially wetted by the caustic phase in the process. Hydrocarbons flow through the shroud parallel to the caustic phase where the hydrogen sulfide and mercaptans are extracted into the caustic phase in the Thiolex section. The two phases disengage, and the caustic flows to the Regen section where the spent caustic is regenerated using air and catalyst in the oxidizer for reuse which converts the extracted mercaptans to disulfides.

The disulfides are removed from the caustic by a fiber-film contactor solvent wash system.

See also: Gas Cleaning.

Thiopaq DeSOx Process

The Thiopaq DeSOx biological process selectively removes and converts Sox in the flue gases to elemental sulfur or hydrogen sulfide. The process is a two-step biological process. It can convert sulfite and sulfate to elemental sulfur. A sodium biophosphate solution quenches and removes particulates and absorbs SOx from the flue gas. The scrubbing liquid is regenerated and recycled to the scrubber.

The heart of the Thiopaq process is the anaerobic and aerobic bioreactors. In these airlift loop reactors, the absorbed sulfite is reduced to sulfide inside the anaerobic reactor in the presence of microorganism with hydrogen. The sulfide is then oxidized under controlled conditions to elemental sulfur via the microorganisms. The produced elemental sulfur has a hydrophilic nature and is separated from the aqueous effluent in a proprietary three-phase separator.

See also: BioDeNOx Process, Gas Cleaning.

Thiopaq Hydrogen Sulfide Removal

The biological Thiopaq process selectively removes and converts hydrogen sulfide and low-boiling mercaptans from gas streams, aqueous streams, and/or low-boiling hydrocarbons to elemental sulfur or sulfate.

The Thiopaq process consists of three integrated process sections. An absorption section to remove the hydrogen sulfide from the gas stream, bioreactors, and a sulfur separation section.

The heart of this process is the bioreactor. In these air lift loop reactors, sulfide is oxidized under controlled conditions to elemental sulfur in the presence of microorganisms. These aerobic organisms use the released energy from the sulfide oxidation for metabolic processes. The elemental sulfur produced has a hydrophilic nature and is separated from the aqueous effluent in a proprietary three-phase separator. The scrubbing step to remove hydrogen sulfide from the gas streams is integrated into the Thiopaq process and regenerates the scrubbing solution, rather than its disposal. Regeneration is possible because the alkalinity consumption due to the absorption of hydrogen sulfide is compensated by the oxidation of hydrogen sulfide to elemental sulfur.

The absorber operates at the pressure of feed and a bioreactor temperature. The bioreactor operates at atmospheric pressure and 30 to 35°C. If the feed is available at a higher temperature, it requires cooling before entering the absorber.

Thorium

Thorium is a naturally occurring, slightly radioactive element. It is widely distributed in nature with an average concentration of 10.5 ppm in the upper crust of the Earth. In general, thorium occurs in relatively small number in

thorium-enriched minerals: thorite, thorianite, monazite, bastnaesite, and thorogummite. However, the main world resources of thorium are coupled with monazite and bastnaesite.

Thorium is a radioactive element that occurs naturally in low concentrations (approximately 10 parts per million) in the Earth's crust. It is approximately three times as abundant as uranium and approximately as abundant as lead or molybdenum. Thorium in its pure form is a silvery-white heavy metal that is approximately as dense as lead. In nature, almost all thorium is thorium-232, although several additional isotopes can be present in small amounts. (Isotopes are different forms of an element that have the same number of protons in the nucleus but a different number of neutrons.) Thorium is a soft, ductile metal that is pyrophoric in powdered form. When heated in air, thorium turnings ignite and burn brilliantly with a white light.

Of the 26 known isotopes of thorium, only 12 have half-lives greater than one second, and of these only 3 have half-lives sufficiently long to warrant a concern. These key isotopes decay very slowly by emitting an alpha particle. The half-lives of thorium-232 (^{232}Th) and thorium-230 (^{230}Th), the isotopes of most concern, are long. The low specific activity of these two isotopes is an indication that these two isotopes are not highly radioactive. The health risks associated with thorium-228 (^{228}Th), which has a half-life of 1.9 years, are commonly included with those for radium-228 (^{228}Ra) because thorium-228 (^{228}Th) cannot persist for an extended period of time in the absence of radium-228 (^{228}Ra).

The nucleus of a thorium atom generally doesn't break up or fission when it is struck by a neutron, which can set off an energy-releasing chain reaction in uranium or plutonium. Instead, the neutron is absorbed; and the most common thorium nucleus, which consists of 90 protons and 142 neutrons, suddenly includes an extra unit, making it much less stable than it was before. Thorium-233 (^{233}Th) is so unstable, in fact, that even when produced in quantity, it soon decays radioactively. Within 23 minutes, half the thorium-233 (^{233}Th) atoms in any given mass will decay by emitting one negative charge each. The loss of each negative charge (a beta particle) in this fashion transforms one of the neutrons inside the affected nucleus into an additional proton. But as soon as the number of protons in a nucleus changes, the atom itself is transformed into a completely different element.

Tidal Barrage

A tidal barrage is a dam-like structure used to capture the energy from masses of water moving in and out of a bay or river due to tidal forces. Instead of damming water on one side like a conventional dam, a tidal barrage first allows water to flow into the bay or river during high tide, and releasing the water back during low tide. This is done by measuring the tidal flow and controlling the sluice gates at key times of the tidal cycle. Turbines are then placed at these sluices to capture the energy as the water flows in and out.

The barrage method of extracting tidal energy involves building a barrage across a bay or river that is subject to tidal flow. Turbines installed in the barrage wall generate power as water flows in and out of the estuary basin, bay, or river. These systems are similar to a hydro dam that produces Static Head or pressure head (a height of water pressure). When the water level outside of the basin or lagoon changes relative to the water level inside, the turbines are able to produce power. The basic elements of a barrage are caissons, embankments, sluices, turbines, and ship locks.

See also: Steam Turbine, Tidal Energy.

Tidal Energy

Tidal energy (also called tidal power) is a form of hydro-power that converts the energy of tides into electricity or other useful forms of power. The tidal forces are periodic variations in gravitational attraction exerted by celestial bodies. These forces create corresponding motions or currents in the oceans of the Earth. Due to the strong attraction to the oceans, a bulge in the water level is created, causing a temporary increase in sea level. When the sea level is raised, water from the middle of the ocean is forced to move toward the shorelines, creating a tide. This occurrence takes place in an unflinching manner, due to the consistent pattern of the moon's orbit around the Earth.

In terms of alternative energy, tidal energy refers to the energy that is harnessed from the tides for practical purposes. The term tidal power is used synonymously as the conversion of tidal energy into a useful form of energy, or more specifically as the generation of electricity from the tides. Tidal power is the only technology that draws on energy inherent in the orbital characteristics of the Earth-Moon system, and to a lesser extent in the Earth-Sun system. Tidal power may be considered a form of hydropower whereby the definition of hydropower is expanded to encompass any type of energy gained from the movement of water. Furthermore, because the Earth's tides are ultimately due to gravitational interaction with the Moon and Sun and the rotation of the Earth, tidal power is practically inexhaustible and classified as a renewable energy resource.

Although not yet widely used, tidal power has potential for future electricity generation. Tides are more predictable than wind energy and solar power. Among sources of renewable energy, tidal power has traditionally suffered from relatively high cost and limited availability of sites with sufficiently high tidal ranges or flow velocities, thus constricting its total availability. However, many recent technological developments and improvements, both in design (e.g., dynamic tidal power, tidal lagoons) and turbine technology (e.g., new axial turbines, cross flow turbines), indicate that the total availability of tidal power may be much higher than previously assumed, and that economic and environmental costs may be brought down to competitive levels.

Because the tidal strength varies greatly depending on location as well as the time of year. Tidal power traditionally involves erecting a dam across the opening to a tidal basin. The dam includes a sluice that is opened to allow the tide to flow into the basin; the sluice is then closed, and as the sea level drops, traditional hydro-power technologies can be used to generate electricity from the elevated water in the basin. In this report, there are three ways of using tidal power, which is tidal stream generator, tidal barrage, and dynamic tidal power.

There are different means to harness tidal energy – the first is to exploit the cyclic rise and fall of the sea level using barrages and the second is to harness local tidal currents, analogous to wind power also called marine current turbine. The generation of tidal energy has same method as it is in the hydroelectric power plants. There are currently three different ways to get tidal energy which are: (i) tidal streams, (ii) barrages, and (iii) tidal lagoons.

Tidal currents below the surface of the water can be harnessed using turbines; however, this often doesn't produce very much energy due to the small area of effect. The advantage of this method is that the machines needed are low cost, have minimal impact on the environment, and do not require further infrastructure.

Another way to harvest tidal energy is with a tidal barrage (also known as impoundment tidal energy), which uses a dam built beneath the water that utilizes tides to gather water. This then water flows through the dam and powers turbines. These dams have a moderate environmental impact, however, leading to the alternative tidal lagoon.

These lagoons are built near bodies of water that will be brought in by the tide to fill them. The water can then flow back into the body of water and power turbines on its way out. Because they don't need to be directly in bodies of water, tidal lagoons are more environmentally friendly. Finally, dynamic tidal power is a way to make normally unusable tides practical. It involves building a bent T-shaped dam out from a coast, and then allowing a head to form on either side of the dam due to tidal shifts from the moon. These would power bi-directional turbines as they leveled out, resulting in a reliable source of energy. This is, however, one of the most expensive forms of tidal energy leading it to be less practical.

For most tidal energy generators, turbines are placed in tidal streams. A tidal stream is a fast-flowing body of water created by tides. A turbine is a machine that takes energy from a flow of fluid. That fluid can be air (wind) or liquid (water). Because water is much more dense than air, tidal energy is more powerful than wind energy. Unlike wind, tides are predictable and stable. Where tidal generators are used, they produce a steady, reliable stream of electricity.

Placing turbines in tidal streams is complex, because the machines are large and disrupt the tide they are trying to harness. The environmental impact could be severe, depending on the size of the turbine and the site of the tidal stream. Turbines are most effective in shallow water. This produces more energy and allows ships to navigate around the turbines. The turbine blades of a tidal generator also turn slowly, which helps marine life avoid getting caught in the system.

Another type of tidal energy generator uses a large dam called a barrage. With a barrage, water can spill over the top or through turbines in the dam because the dam is low. Barrages can be constructed across tidal rivers, bays, and estuaries. Turbines inside the barrage harness the power of tides the same way a river dam harnesses the power of a river. The barrage gates are open as the tide rises. At high tide, the barrage gates close, creating a pool, or tidal lagoon. The water is then released through the turbines of the barrage, thereby creating energy at a rate that can be

controlled. The doors and the turbines installed along a barrage or dam extend through the opening of the tidal basin, such as an estuary or a dam. A diverse level of fluid is produced on the sides of the barrage by the tides. The doors are opened as this difference gets increased, causing the water to flow out. This water thus strikes with turbine blades and causes them to rotate, and electric power is generated.

The environmental impact of a barrage system can be quite significant. The land in the tidal range is completely disrupted. The change in water level in the tidal lagoon might harm plant and animal life. The salinity inside the tidal lagoon lowers, which changes the organisms that are able to live there. As with dams across rivers, fish are blocked into or out of the tidal lagoon. Turbines move quickly in barrages, and marine animals can be caught in the blades. With their food source limited, birds might find different places to migrate. A barrage is a much more expensive tidal energy generator than a single turbine. Although there are no fuel costs, barrages involve more construction and more machines. Unlike single turbines, barrages also require constant supervision to adjust power output.

The final type of tidal energy generator involves the construction of tidal lagoons. A tidal lagoon is a body of ocean water that is partly enclosed by a natural or manmade barrier. Tidal lagoons might also be estuaries and have fresh-water emptying into them. A tidal energy generator using tidal lagoons would function much like a barrage. Unlike barrages, however, tidal lagoons can be constructed along the natural coastline. A tidal lagoon power plant could also generate continuous power. The turbines work as the lagoon is filling and emptying.

The technology that is used to produce electricity using the difference between the low and high tides is similar to the one use on the generation of electricity on the traditional hydroelectric power plants. The use of the tidal energy requires a dam or barrage across a shallow area, preferably an estuary, bay or gulf of high tidal range where the difference on the low and high tide have to be at least 5 meters. The tide basins are filled and empty every day with the flood tides when the water level rises and with the ebb tides when the water level falls. On the barrage, there are low-head turbines and sluices gates that allow the water to flow from one side of the barrage to inside the tidal basin. This difference on elevation of the water level creates a hydrostatic head that generates electricity. There are different modes to generate electricity using the barrage systems: (i) ebb generation, (ii) flood generation, (iii) two-way generation, (iv) pumping, and (v) double basin.

Using the ebb generation method, the incoming water (flood tide) is allowed to flow freely to fill the basin until high tide, then the sluices are close and water are retained on one side of the barrage. When the level of the water outside of the barrage decreases (ebb tide) sufficiently to create a hydrostatic head between the open waters and the tide basin, the sluices are open and water flows through the turbines and generate electricity. Once the head is low, the sluices gates are open and the basin is filled again.

Using the flood generation method, during the flood tide, the sluices gates and low-head turbines are kept closed to allow the water level outside of the barrage to increase. Once a hydrostatic head is created, the sluices gates are opened and the water flows through the turbines into the basin. This mode is less efficient than the ebb mode.

The two-way generation method uses both the ebb and the flood tide to generate electricity. The main problem with this type of mode is that the turbines must work both ways when water enters or exits the basin. On the pumping generation method, the hydrostatic head can be increased, reversing the power and turning the turbine-generator into a pump-motor. During the generation, the energy that was use is returned.

In the flood generation method, the basin is filled through the turbines, which generate at tide flood. This is generally much less efficient than ebb generation because the volume contained in the upper half of the basin (which is where ebb generation operates) is greater than the volume of the lower half (filled first during flood generation). Therefore the available level difference in turbine power produce – between the basin side and the sea side of the barrage – reduces more quickly than it would in ebb generation. Rivers flowing into the basin may further reduce the energy potential, instead of enhancing it as in ebb generation.

In the pumping method, turbines are able to be powered in reverse by excess energy in the grid to increase the water level in the basin at high tide (for ebb generation). This energy is more than returned during generation because power output is strongly related to the head. If water is raised 2 ft. (61 cm) by pumping on a high tide of 10 ft. (3 m), this will have been raised by 12 ft. (3.7 m) at low tide. The cost of a 2 ft. rise is returned by the benefits of a 12 ft. rise. This is since the correlation between the potential energy is not a linear relationship, rather, is related by the square of the tidal height variation.

Another form of energy barrage configuration is that of the dual basin type. With two basins, one is filled at high tide and the other is emptied at low tide. Turbines are placed between the basins. Two-basin schemes offer

advantages over normal schemes in that the generation time can be adjusted with high flexibility, and it is also possible to generate almost continuously. In normal estuarine situations, however, two basin schemes are expensive to construct due to the cost of the extra length of barrage. There are some favorable geographies, however, which are well suited to this type of scheme.

Tidal pools are independent enclosing barrages built on high-level tidal estuary land that trap the high water and release it to generate power. Two lagoons operating at different time intervals can guarantee continuous power output. Enhanced pumped storage tidal series of lagoons raises the water level higher than the high tide, and uses intermittent renewable energy for pumping.

While the methods described above use one tidal basin, in the double basin method, the turbines are placed between the basins. The main basin will use the ebb generation mode to operate and pump water with part of the energy that is generated to and from the second basin to generate electricity continuously.

The environmental impact of tidal lagoons is minimal. The lagoons can be constructed with natural materials like rock. They would appear as a low breakwater (sea wall) at low tide, and be submerged at high tide. Animals could swim around the structure, and smaller organisms could swim inside it. Large predators like sharks would not be able to penetrate the lagoon, so smaller fish would probably thrive. Birds would likely flock to the area. However, the energy output from generators using tidal lagoons is likely to be low.

See also: Ocean Energy, Steam Turbine, Wave Energy.

Tidal Stream Generator

A tidal stream generator, often referred to as a tidal energy converter (TEC), is a machine that extracts energy from moving masses of water, in particular tides, although the term is often used in reference to machines designed to extract energy from run of river or tidal estuarine sites.

Tidal stream generators draw energy from water currents in much the same way as wind turbines draw energy from air currents. However, the potential for power generation by an individual tidal turbine can be greater than that of similarly rated wind energy turbine. The higher density of water relative to air (if the density of air = 1, the density of water = approximately 800) means that a single generator can provide significant power at low tidal flow velocities compared with similar wind speed. Also, since power varies with the density of medium and the cube of velocity, water speeds of nearly one-tenth the speed of wind provide the same power for the same size of turbine system; however, this limits the application in practice to places where tide speed is at least 2 knots (1 meter per second) even close to a neap tide, which is a tide that occurs just after the first or third quarters of the moon when there is least difference between high and low water. Furthermore, at higher speeds in a flow between 2 and 3 meters per second in seawater, a tidal turbine can typically access four times as much energy per rotor swept area as a similarly rated power wind turbine.

Tidal stream generators are the least ecologically damaging among the three main forms of tidal power generation. Various turbine designs have varying efficiency and therefore varying power output.

Timber Belts

Wood is an organic material, a natural composite of cellulose fibers embedded in a matrix of lignin. Wood is produced as secondary xylem in the stems of trees. Wood is one of the most abundant and environmentally friendly biomass resources.

The main advantage of using wood as a fuel is that wood is a renewable resource, offering a sustainable, dependable supply. Other advantages include the fact that the amount of carbon dioxide (CO₂) emitted during the burning process is typically 90% less than when burning fossil fuel. Wood fuel contains minimal amounts of sulfur and heavy metals, and use of wood as a fuel is not a threat to pollution by acid rain, and particulate emissions are controllable.

Timber belts are multiple row field windbreaks that are planted with commercially valuable, fast-growing trees (such as hybrid poplar or hybrid willow) to provide conservation benefits, improve adjacent crop yields, diversify

on-farm income sources, and produce commercially valuable wood products. Various planting configurations have been developed that provide wind protection for soils and crops, and yield sufficient biomass to make wood harvest economical. Tree rows are oriented perpendicular to the prevailing wind to reduce wind velocity and improve the microclimate within the sheltered zone to enhance the production of adjacent crops. Because of their rapid growth and range of marketable products, hybrid poplars fit well into the timber belt concept. The strategy is to harvest half of the rows in a timber belt at age 7 to 12, while the other half are left to provide continued wind protection. Within a few years after the stumps have sprouted and re-established sufficient wind protection, the remaining rows are harvested. In this way, continuous wind protection and associated economic benefits to adjacent crops can be achieved.

See also: Biomass, Timberland, Wood, Wood Biomass.

Timberland

Forest land is land that is 10% forested by trees of any size and includes land that may have been naturally or artificially regenerated. Thus, timberland is forest land that is available to harvest and capable of productivity over a long period of time in terms of producing or is capable of producing crops of industrial wood, and that is not withdrawn from timber utilization by statute or administrative regulation.

Tires – Devulcanization

Goodyear Rubber and Tire Company developed a unique process for devulcanizing scrap tire rubber using a novel supercritical fluid technology.

The technology uses sec-butanol [2-butanol, $\text{CH}_3\text{CH}_2\text{CH}(\text{OH})\text{CH}_3$] as a supercritical fluid, which functions as a pyrolysis medium and also as a chain cleavage agent. The solvent not only facilitates the cleavage of carbon-sulfur (C-S) and carbon-carbon (C-C) bonds reaction in a near-homogeneous state, but also dissolves the reacted fragments and takes them away from other reactive intermediates. The solvent, sec-butanol, is fully recoverable and reusable in the process.

This strong supercritical behavior of sec-butanol may be attributed to its unique molecular structure which has the center carbon connected to all four different functional fragments, thereby maximizing the quadruple moments. They further enhanced their process by employing a co-solvent process, by which the amount of sec-butanol needed can be significantly reduced for the process without losing the efficiency. As a co-solvent to this process, carbon dioxide was found to be effective.

See also: IFP Process, Tires – Dry Distillation, Tires – Scrap.

Tires - Dry Distillation

The dry distillation of spent tires can be operated with either shredded or whole tires without removing metallic wires.

The tires enter the top of the distillation tower via a conveyor belt. Once filled, the tower is sealed to prevent the gaseous product from escaping. Combustion is initiated by burners located at the bottom of the tower and then sustained by the introduction of process air. As combustion continues, the hot gas rises to the top of the tower. The rising gas has a dual purpose. The first is to assist in the combustion of the tires located at the top of the tower. Secondly, the rising of the gas acts in the same manner as a traditional distillation column for the separation of the end products. The gas is cooled down by the gas cooler. Part of the gas is liquefied and recovered in the form of oil. Recovered oil is equivalent to Class B heavy oil. The residue (char and tire cord) is removed from the bottom tower by a conveyor. Once cooled, the residue is separated into individual components.

See also: IFP Process, Tires – Scrap.

Tires – Hydrogenation

Hydrogenation, unlike pyrolysis or similar processes, is a chemical synthesis process. In simplistic terms, it entails the addition of hydrogen, the element, which is removed from oil, to make synthetic rubber. By adding the appropriate amount of hydrogen to the waste tires, the rubber can be returned to its original form.

By adding hydrogen, devulcanization, saturation, carbon-carbon bond cleavage reactions are induced. In some sense, the process is quite similar to the hydrotreating process of heavy oil and residua.

See also: Hydroprocesses.

Tires – Pyrolysis

In the process, the scrap tires are first reduced in size, by grinding, chipping, or pelletizing, then sent to a clarifier for the removal of the scrap metal.

The method involves use of a temperature is initially at 100°C, while the rubber is loaded into the reactor. After one hour, the temperature is ramped to 300-500 °C, depending on the process. The reactor is held at the final temperature for a minimum of two hours. The gas fraction is sent to a distillation apparatus for subsequent purification and analysis. The oil and char are separated using a second column.

See also: Tires – Scrap.

Tires – Scrap

The United States alone generates over millions of waste tires each year. Although numerous recycling programs and methods have been deployed over the years, a large percentage of these tires still end up in landfills. Scrap tires are almost immune to biodegradation and will survive in landfills for years, if not decades.

Converting these waste tires into usable energy through environmentally responsible technology provides a significant opportunity (Table T-1).

Table T-1 Scrap tire pyrolysis.

Feedstock	Process	Products	Process	Use
Scrap tires	Pyrolysis	Gases	Gas cleaning	Heat and power
Oil	Refining	Fuel oil		
		Char	Purification	Activated carbon
				Filler

Waste tire pyrolysis involves the thermal degradation in the absence of oxygen. The benefit of this application is the conversion of waste tires into value-added products such as olefins, chemicals, and surface-activated carbon.

The production of significant quantities of valuable high-molecular-weight olefins to obtain curable and moldable olefins (molecular weight >15,000) would overcome current economic barriers. These are typically produced in small quantities because the process temperature is high. At high temperature, vulcanized rubbers are quickly decomposed to low-molecular-weight olefins (Mw 300-400). High-molecular-weight compounds can be generated by low-temperature pyrolysis. However, lower temperature will require longer process times. New technological breakthroughs will be necessary for the commercialization of low-temperature pyrolysis. Other technologies that are being developed include (i) microwave pyrolysis, (ii) ultrasonic devulcanization, (iii) supercritical fluid depolymerization, and (iv) catalytic processes.

Microwave pyrolysis is the use of microwaves to heat objects more uniformly than conventional heating methods. Microwave heating requires shorter heating times. Microwave pyrolysis will result in relatively high-molecular-weight olefins and a high proportion of valuable products such as ethylene, propylene, butene, aromatics, etc. The

short process time also contributes to a reduction in the process cost. Moreover, for microwave heating, the shape of the tire chip is less important compared to the requirements of conventional heating. Whole tires or larger chips can be processed using microwave pyrolysis, which greatly reduces pre-processing cost.

Ultrasonic devulcanization involves the use of sonic energy to break down sulfur-carbon chemical bonds in tires. Chipped tires are heated to approximately 200°C (390°F) then subjected to 20,000 cycles per second of ultrasonic energy (just above the highest frequency the human ear can discern) at pressures reputedly up to several thousand pounds per square inch. The rubber is transformed from a solid to a highly viscous fluid within milliseconds. With additional curative agents, the viscous material can be molded into new products.

Supercritical water can be used to controllably depolymerize the rubber compounds. This approach requires lower temperatures (approximately 400°C, 750°F) and shorter processing times. Tire compounds are decomposed to high-molecular-weight olefins or oil.

Use of catalysts can reduce processing temperature or time. Reduced temperature and time can result in either higher-molecular-weight olefins or an increasing proportion of valuable substances. The advantage of catalysts is that no new equipment or knowledge is required.

See also: Waste, Municipal Solid Waste, Pyrolysis.

Ton, Tonne

One U.S. ton (short ton) is equivalent to 2,000 pounds. One Imperial ton (long ton or shipping ton) is equivalent to 2,240 pounds.

One metric ton (tonne) is equivalent to 1,000 kilograms (2,205 pounds). One oven-dry ton or tonne (ODT, sometimes termed bone-dry ton/tonne) is the amount of wood that weighs one ton/tonne at 0% moisture content.

One green ton/tonne refers to the weight of undried (fresh) biomass material – the moisture content must be specified if green weight is used as a fuel measure.

Torrefaction

Untreated woody biomass has a relatively low energy density, high moisture content and is difficult to comminute into small particles. These properties make the transport of wood relatively expensive. After drying, it can regain moisture and may rot during storage. Furthermore, enhancement of the energy density is advisable because a large amount of wood is required to replace an equivalent amount of coal in applications such as combustion and gasification. A technology that could help to overcome these problems is a thermal processing step known as torrefaction.

Torrefaction represents the thermal treatment of biomass (mainly wood) in the absence of oxygen for 15-60 min at 200 to 300°C (390 to 570°F) and at atmospheric pressure. As a result, biomass (such as wood) is converted into a carbonaceous product. Torrefaction transformation is highly efficient – with an 85 to 95% conversion rate.

The energy spent on torrefaction is fully paid off by the 8 to 10 times lower energy consumption of torrefied wood milling compared to fresh wood milling. As the properties of torrefied wood and coal are similar, the conventional coal-feeding facilities can be used for torrefied wood.

In terms of the process, torrefaction is a mild thermal treatment at a temperature of 250 to 300°C (480 to 570°F), which converts solid biomass into a more brittle and easily pulverized material that can be treated and handled just like coal. This torrefied product is often called bio-coal.

Pulverized torrefied biomass can be treated just as coal, and most entrained flow gasifiers designed for coal can be smoothly converted for torrefied bio-coal without much adaptation. The gases produced during the torrefaction process may be used for torrefaction, thus accomplishing a self-energy supply cycle.

Dehydration and decarboxylation reactions cause a mass loss of the wood, whereas the lower heating value of the wood is largely conserved. Deciduous wood types (beech and willow) and straw were found to produce more volatiles than coniferous wood (larch), especially more methanol and acetic acid. These originate from acetoxy-groups and from methoxy-groups present as side chains in xylose units present in the xylan-containing hemicellulose fraction.

The torrefied wood product has a brown/black color, reduced volatile content, and increased energy density. It has favorable properties for application as a fuel for gasification and/or (co-)combustion.

The chemical properties of torrefied wood could also be related to its mechanical properties, depending on the extent of decomposition of the hemicellulose fraction in the torrefaction process (and possibly depolymerization of the cellulose fraction); the friability can be expected to increase.

Town Gas

The term town gas is a generic term referring to manufactured gas produced for sale to consumers and municipalities. The terms coal gas, manufactured gas, producer gas, and syngas (synthetic natural gas, SNG) are also used for gas produced from coal. Depending on the processes used for its creation, town gas is a mixture of hydrogen, carbon monoxide, methane, and volatile hydrocarbons with small amounts of carbon dioxide and nitrogen as impurities. Town gas has a heat content of approximately 600 Btu/ft³.

Prior to the development of natural gas supplies and transmission in the United States during 1940s and 1950s, virtually all fuel and lighting gas was manufactured, and the by-product coal tar was an important feedstock for the chemical industry. The development of manufactured gas paralleled that of the industrial revolution and urbanization.

Toxicity Characteristic Leaching Procedure

The toxicity characteristic leaching procedure (TCLP) is a soil sample extraction method for chemical analysis.

Landfill leachate is a notoriously complex substance to deal with, primarily because of its ever-changing composition. In that sense, the TCLP is a procedure for determining the decay of release of a material from a landfill and can be used as a gauge of the decay of organic material to produce liquids and landfill gas.

The toxicity characteristic leaching procedure comprises four fundamental procedures which are (i) sample preparation for leaching, (ii) sample leaching, (iii) preparation of leachate for analysis, and (iv) leachate analysis and is generally useful for classifying waste material for disposal options. Extremely contaminated material is expensive to dispose, and grading is required to ensure safe disposal and to avoid paying for disposal of clean fill. The main problem is that the toxicity characteristic leaching procedure test is based on the assumption that the waste material will be buried in landfill along with organic material. Organic matter is not really buried with other waste anymore (composting usually applies), and other leachate techniques may be more appropriate.

As an example of the method, the pH of the sample material is first established, and then leached with an acetic acid/sodium hydroxide solution at a 1:20 mix of sample to solvent. The leachate solution is sealed in extraction vessel for general analytes, or possibly pressure sealed as in zero-headspace extractions (ZHE) for volatile organic compounds, cyanides, or sulfites, and tumbled for 18 hours to simulate an extended leaching time in the ground.

To date, landfill leachate has not been designated as a potential biofuel source (because of the complex variables that dictate the composition of the leachate) but that time may arise after stricter regulations regarding waste segregation are enacted.

Trace Element

A trace element is a chemical element whose concentration is less than 1,000 ppm w/w or 0.1% w/w of the composition of the substance. Many types of biomass contain trace of elements. Trace elements also known as trace minerals, are the chemical components that naturally occur in soil, plant, and wildlife in minute concentrations. They are necessary for the optimal development and metabolic functioning such as proper cell metabolism, effective immune function, and healthy reproduction of humans. Their role and homeostasis in living organisms vary. There are 19

known trace elements that are categorized into three groups: (i) essential elements, (ii) probably essential elements, and (iii) potentially toxic elements.

Many trace elements are concentrated in particulate emissions; it is these extremely small particles that are the most difficult to eliminate and which are potentially the most harmful since they have the ability to enter, directly or indirectly, the human physiological system.

Transesterification

Transesterification is a chemical process in which an alcohol reacts with the triglycerides in vegetable oil or animal fats, separating the glycerin and producing biodiesel.

The purpose of transesterification of vegetable oils to their methyl esters (biodiesel) process is to lower the viscosity of the oil. The transesterification reaction is affected by alcohol type, the molar ratio of glycerides to alcohol, the type and amount of catalyst, reaction temperature, reaction time, and free fatty acids and the water content of vegetable oils or animal fats. The transesterification reaction proceeds with or without a catalyst by using primary or secondary monohydric aliphatic alcohols having 1–8 carbon atoms as follows:

Generally, the reaction temperature near the boiling point of the alcohol is recommended. The reactions take place at low temperatures [approximately 65°C, 150°F] and at modest pressures (30 psi). Biodiesel is further purified by washing and evaporation to remove any remaining methanol. The oil (87%), alcohol (9%), and catalyst (1%) are the inputs in the production of biodiesel (86%), the main output. Pretreatment is not required if the reaction is carried out under high pressure and high temperature (240°C, 465°F), where simultaneous esterification and transesterification take place with maximum yield obtained at temperatures ranging from 60 to 80°C (140 to 175°F) at a molar ratio of 6:1.

Vegetable oil-based biodiesel has been shown to be comparable to conventional diesel. It has low viscosity, low flash points, high vapor pressure, and is easy to process. Animal fats are preferred to vegetable oils because they are much cheaper and there is a much larger supply. Animal fats cannot be used directly because their physical properties cause poor atomization, poor vapor-air mixing, low pressure, incomplete combustion, and engine deposits. Transesterification is a means to improve all of these disadvantages. Biodiesel from animal fats have higher calorific values and cetane numbers but are less stable to oxidation and have a higher cold filter plugging point as compared to biodiesel from vegetable oils.

In the conventional synthesis of biodiesel, bio-esters (bio-oils) undergo transesterification in the presence of methanol and base (usually sodium hydroxide) (Figure 10.2). In this reaction, the bio-oil (a tri-ester or triglyceride) reacts with methanol and a catalyst to produce glycerol and three new methyl-substituted esters. Mechanistically, the triglyceride derivatives are converted to diglyceride derivatives, which are in turn converted to monoglycerides. Finally, the monoglyceride is converted to glycerol. A high ratio of methanol to oil is required for transesterification. The high ratio of methanol also helps the glycerol that is formed phase separate (Figure 10.3). Once the glycerol phase separates from the biodiesel, the biodiesel is purified via water washing, vacuum drying, and filtration. The energy-intensive purification of the biodiesel is one of the many reasons its processing is not energy efficient. The alcohols employed in the transesterification are generally short chain alcohols such as methanol, ethanol, propanol, and butanol. It was reported that when transesterification of soybean oil using methanol, ethanol, and butanol was performed, 96–98% of ester could be obtained after 1 hour.

Chemically, transesterified biodiesel comprises a mix of mono-alkyl esters of long chain fatty acids. The most common form uses methanol to produce methyl esters as it is the cheapest alcohol available, though ethanol can be used to produce an ethyl ester biodiesel and higher alcohols such as iso-propanol and butanol have also been used. Using alcohols of higher molecular weights improves the cold flow properties of the resulting ester, at the cost of a less efficient transesterification reaction.

Any free fatty acids in the base oil are either (i) the fatty acids are converted to soap and removed from the process, or (ii) the fatty acids are esterified (yielding more biodiesel) using an acidic catalyst. After this processing, unlike

straight vegetable oil, biodiesel has combustion properties similar to those of diesel produced from crude oil, and can replace it in most current uses.

A by-product of the transesterification process is the production of glycerin (glycerol). For every unit of biodiesel that is manufactured, 0.1 unit of glycerol is produced. Originally, there was a valuable market for the glycerol, which assisted the economics of the process as a whole. However, with the increase in global biodiesel production, the market price for this crude glycerol (containing 20% water and catalyst residues) is lower and affords an operational challenge. Usually, the crude glycerol has to be purified, typically by performing vacuum distillation after which the refined glycerol (>98% purity) can then be utilized directly, or converted into other products.

Production of biodiesel is dependent upon a number of variables. These include: (i) the types of feedstock, (ii) catalyst, (iii) solvent, (iv) temperature and pressure, and (v) ratio of alcohol to oil. The feedstock usually includes animal tallow (animal fat) and waste cooking vegetable oil. Most studies on animal tallow focus on freshly collected animal tallow, which is low in free fatty acid value. If the animal tallow is not immediately converted, the acid value increases due to hydrolysis caused by the presence of water and degradation. Free fatty acids can react with basic catalysts, thus using up the catalyst, and the so-called soap products are difficult to separate from the desired biodiesel. Waste cooking oils also have higher amounts of free fatty acids and higher levels of moisture.

The high levels of moisture and free fatty acids are usually dealt with through some sort of acidic pre-treatment that causes acid catalysed transesterification of the free fatty acids, followed by alkaline transesterification of the bio-oils. Numerous studies, in fact, have introduced an acidic pre-treatment or simply used an acidic catalyst when the feedstock has a large amount of free fatty acids. For example, a recent study has indicated that an acidic pre-treatment (2% w/w H_2SO_4 , 65°C/149°F, 5 hours, 6:1 methanol to lard) of highly acidic animal tallow, followed by conventional biodiesel production, led to a biodiesel product with 66.2% w/w yield of approximately 96% purity.

Alcoholysis

The transesterification of triglycerides by supercritical methanol (SCM), ethanol, propanol, and butanol (alcoholysis) has proved to be the most promising process.

The transesterification process is used to produce biodiesel from biomass, or some alternative source as opposed to crude oil-derived biodiesel. Biodiesel is advantageous compared to conventional biodiesel in that it is renewable, biodegradable, non-toxic, and has low emissions. Recent research has suggested that biodiesel can be produced from waste oils such as used cooking vegetable oil and from inedible animal tallow collected from slaughterhouses and other meat processing units.

Vegetable oil-based biodiesel has been shown to be comparable to conventional diesel. It has low viscosity, low flash points, high vapor pressure, and is easy to process. Animal fats are preferred to vegetable oils because they are much cheaper and there is a much larger supply. Animal fats cannot be used directly because their physical properties cause poor atomization, poor vapor-air mixing, low pressure, incomplete combustion, and engine deposits. Transesterification is a means to improve all of these disadvantages. Biodiesel from animal fats have higher calorific values and cetane numbers but are less stable to oxidation and has a higher cold filter plugging point as compared to biodiesel from vegetable oils.

In the conventional synthesis of biodiesel, the transesterification occurs in the presence of methanol and base (usually sodium hydroxide). In this reaction, the bio-oil (a tri-ester or triglyceride) reacts with methanol and a catalyst to produce glycerol and three new methyl-substituted esters. Mechanistically, the triglycerides are converted to diglycerides, which are in turn converted to monoglycerides. Finally, the monoglyceride is converted to glycerol. A high ratio of methanol to oil is required for transesterification. The high ratio of methanol also helps the glycerol that is formed phase separate. Once the glycerol phase separates from the biodiesel, the biodiesel is purified via water washing, vacuum drying, and filtration. The energy intensive purification of the biodiesel is one of the many reasons its processing is not energy efficient.

Production of biodiesel is dependent upon a number of variables. These include (i) the feedstock, (ii) the catalyst, (iii) the solvent, (iv) the temperature and the pressure, and (v) the ratio of alcohol to the oil.

The feedstock usually includes animal tallow (animal fat) and waste cooking vegetable oil. Most studies on animal tallow focus on freshly collected animal tallow, which is low in free fatty acid value. If the animal tallow is not immediately converted, the acid value increases due to hydrolysis caused by the presence of water and degradation. Free fatty acids can react with basic catalysts, thus using up the catalyst, and the so-called soap products are difficult

to separate from the desired biodiesel. Waste cooking oils also have higher amounts of free fatty acids and higher levels of moisture.

The high levels of moisture and free fatty acids are usually dealt with through acidic pre-treatment that causes acid-catalyzed transesterification of the free fatty acids, followed by alkaline transesterification of the bio-oils. Numerous studies, in fact, have introduced an acidic pre-treatment or simply used an acidic catalyst when the feedstock has a large amount of free fatty acids.

Conventionally, alkaline bases are used as the *catalyst* for transesterification; however, acidic catalysts are also beginning to be used. Common basic catalysts used include sodium hydroxide, potassium hydroxide, or their alkoxides or carbonates. Acidic catalysts commonly used are sulfuric acid and hydrochloric acid. Novel enzymatic catalysts are being tested, and scientific literature indicates that they show excellent activity and reduction in undesired co-products; however, they have significantly higher production costs.

Typically, homogenous strong bases are used as the catalyst for biodiesel production; however, there have been numerous studies on heterogeneous catalysts. Heterogeneous catalysts are preferred in large-scale productions because of their ease of separation. Obviously, any new catalyst must be inexpensive since the final product (biodiesel) must be inexpensive. Thus, egg shells have been proposed as potential catalysts for biodiesel production. When 3% w/w calcined egg shells (1,000°C, 1,830°F, 2 hours) were added to a 9:1 molar ratio mixture of methanol and oil, the biodiesel yield exceeded 95% after three hours. The reaction conditions and yield are similar to the homogenous catalytic reaction, and there is, in this case, the benefit of using a low-cost, heterogeneous catalyst.

The most common alcohols used are methanol and ethanol; however, methanol is used more frequently because it is lower in cost. When methanol is used as the solvent, the products are methyl esters. Ethanol is being further investigated because the viscosities of ethanol-ethyl ester mixtures are lower, and ethanol can be produced from renewable or waste resources. Furthermore, ethanol separates from glycerol more effectively.

Transesterification can occur at room temperature if the reaction is left long enough. However, usually, the temperature is kept close to the boiling point of the alcohol used at atmospheric pressure. It has been noted, though, that optimal reaction temperature and pressures depend upon the type and quality of the waste cooking oil being processed. Alcohol in excess of the stoichiometric proportion necessary is commonly used. For acid-catalyzed conversion of oils with high amounts of free fatty acids, much higher ratios are used compared to base-catalyzed transesterification. Specifically, the ratios can range from 6:1 alcohol to oil for base-catalyzed esterification all the way to 250:1 for acid-catalyzed reactions.

Biodiesel produced from waste has been shown to be comparable to biodiesel produced from conventional sources. For example, the engine performance by tallow biodiesel is comparable with the performance by pure diesel fuel without any engine modifications in a direct injection diesel engine. However, tallow biodiesel cannot be used in cold weather conditions because of its low pour point. If the fuel product is used in boilers for heat generation, it can be used without mixing with conventional biodiesel. Furthermore, biodiesel can be mixed until desired qualities are achieved. For example, blending 20% v/v animal-fat derived biodiesel with conventional diesel produces a cetane number higher than conventional diesel.

Using wastes as sources for biodiesel has several major advantages: (i) avoid the fuel versus food debate since the feedstock is non-edible, (ii) reduce the final cost of the fuel since non-edible feed stock is typically cheaper, (iii) recycle waste, and (iv) the produced fuel is biodegradable. However, the production of biodiesel also has its disadvantages. Transesterification is normally achieved using alkaline catalysts. These catalysts are corrosive and form unwanted by-products that are expensive to separate. Homogenous acid catalysts can also be used, but these are difficult to recycle, operate at high temperatures, and have significant corrosion and environmental issues.

Recently, a catalyst-free method was developed for biodiesel production by employing supercritical methanol. The supercritical treatment at 350°C (650°F) and approximately 6,000 psi with a molar ratio of 42 in methanol is the optimum condition for transesterification of rapeseed oil to biodiesel fuel.

To achieve more moderate reaction conditions, further effort was made through the two-step preparation. In this method, oils/fats are, first, treated in subcritical water for hydrolysis reaction to produce fatty acids. After hydrolysis, the reaction mixture is separated into oil phase and water phase by decantation. The oil phase (upper portion) is mainly fatty acids, while the water phase (lower portion) contains glycerol in water. The separated oil phase is then mixed with methanol and treated at supercritical condition to produce FAME thorough methyl esterification. After removing unreacted methanol and water produced in reaction, FAME can be obtained as biodiesel. Therefore, in

this process, methyl esterification is the main reaction for FAME formation, while in the one-step method, transesterification is the major one.

Reaction by supercritical methanol has some advantages such as (i) glycerides and free fatty acids are reacted with equivalent rates, (ii) the homogeneous phase eliminates diffusive problems, (iii) the process tolerates great percentages of water in the feedstock catalytic process require the periodical removal of water in the feedstock or in intermediate stage to prevent catalyst deactivation, (iv) the catalyst removal step is eliminated, and (v) if high methanol/oil ratios are used, total conversion of the oil can be achieved in a few minutes. Some disadvantages of the one-stage supercritical method are clear and are (i) the process operates at very high pressures, (ii) the high temperatures used in the process bring along proportionally high heating and cooling costs, (iii) high methanol/oil ratios, which are typically set at 42 and involve high costs for the evaporation of the unreacted methanol, and (iv) the process as posed to date does not explain how to reduce free glycerol to less than 0.02% as established in a variety of international standards.

Biodiesel can be used in any application where conventional diesel is used. For example, tests in light and heavy trucks showed few differences other than the requirement for more frequent oil changes because of build-up in an engine crankcase. Using wastes as sources for biodiesel has several major advantages: (i) avoid the fuel versus food debate since the feedstock is non-edible, (ii) reduce the final cost of the fuel since non-edible feed stock is typically cheaper, (iii) recycle waste, (iv) burning biodiesel does not contribute to net atmospheric carbon dioxide levels, and (v) produced fuel is biodegradable. Production of biodiesel also has its disadvantages. Transesterification is normally achieved using alkaline catalysts. These catalysts are corrosive and form unwanted by-products that are expensive to separate. Homogenous acid catalysts can also be used, but these are difficult to recycle, operate at high temperatures, and have significant corrosion and environmental issues.

Catalytic Transesterification

Transesterification reactions can be catalyzed by alkalis or enzymes. The catalytic transesterification of vegetable oils with methanol is an important industrial method used in biodiesel synthesis.

Also known as methanolysis, this reaction is well studied and established using acids or alkalis, such as sulfuric acid or sodium hydroxide as catalysts. However, these catalytic systems are less active or completely inactive for long chain alcohols. Usually, industries use sodium or potassium hydroxide or sodium methoxide or potassium methoxide as a catalyst since they are relatively cheap and quite active for this reaction. Enzyme-catalyzed procedures, using lipase as a catalyst, do not produce side reactions, but the lipases are expensive for industrial-scale production and a three-step process was required to achieve a 95% conversion.

The acid-catalyzed process is useful when a high amount of free acids is present in the vegetable oil, but the reaction time is long (48 to 96 hours), even at the boiling point of the alcohol, and a high molar ratio of alcohol is needed (20:1 wt/wt to the oil).

The transesterification process is catalyzed by alkaline metal alkoxides, and hydroxides, as well as sodium or potassium carbonates. Alkali-catalyzed transesterification with short-chain alcohols, for example, generates high yields of methyl esters in short reaction times. The alkaline catalysts show high performance for obtaining vegetable oils with high quality, but a question often arises; that is, the oils contain significant amounts of free fatty acids which cannot be converted into biodiesels but to a lot of soap. These free fatty acids react with the alkaline catalyst to produce soaps that inhibit the separation of the biodiesel, glycerin, and wash water.

Triglycerides are readily transesterified in a batch operation in the presence of alkaline catalyst at an atmospheric pressure and at a temperature of approximately 60 to 70°C (140 to 158°F) with an excess of methanol. It often takes at least several hours to ensure the alkali (NaOH or KOH) catalytic transesterification reaction is complete. Moreover, removal of these catalysts is technically difficult and brings extra cost to the final product. Nevertheless, they are a good alternative since they can give the same high conversions of vegetable oils just by increasing the catalyst concentration to 1 or 2 mol%. Alkaline metal alkoxides (as CH_3ONa for the methanolysis) are the most active catalysts since they produce high yields (>98%) in short reaction times (30 minutes) even if they are applied at low molar concentrations (0.5 mol%).

The transesterification process is catalyzed by sulfuric, hydrochloric, and organic sulfonic acids. In general, acid-catalyzed reactions are performed at high alcohol-to-oil molar ratios, low-to-moderate temperatures and

pressures, and high acid catalyst concentrations. These catalysts produce high yields in alkyl esters, but these reactions are slow, requiring typically temperature above 100°C (212°F) and more than 3 h to complete the conversion.

Enzyme (such as lipase)-catalyzed reactions have advantages over traditional chemical-catalyzed reactions: the generation of no by-products, easy product recovery, mild reaction conditions, and catalyst recycling. Also, enzymatic reactions are insensitive to free fatty acids and water content in waste cooking oil. As for the enzyme-catalyzed system, it requires a much longer reaction time than the other two systems. The enzyme reactions are highly specific and chemically clean. Because the alcohol can be inhibitory to the enzyme, a typical strategy is to feed the alcohol into the reactor in three steps of 1:1 mole ratio each. The reactions are slow, with a three-step sequence requiring from 4 to 40 h, or more. The reaction conditions are modest, from 35 to 45°C (85 to 115°F). The main problem of the enzyme-catalyzed process is the high cost of the lipases used as a catalyst.

Synthesis of biodiesel using enzymes such as *Candida antarctica*, *Candida rugosa*, *Pseudomonas cepacia*, immobilized lipase (Lipozyme RMIM), *Pseudomonas* sp., and *Rhizomucor miehei* is reported in the literature. The best yield 98% (w/w) was obtained by using *Pseudomonas cepacia* lipase immobilized on celite at 50°C (122°F) in the presence of 4 to 5% w/w water in 8 hours.

Process Parameters

The main factors affecting transesterification are the molar ratio of glycerides to alcohol, catalyst, reaction temperature and pressure, reaction time, and the contents of free fatty acids and water in oils.

The free fatty acids and moisture content are key parameters for determining the viability of the vegetable oil transesterification process. In the transesterification, free fatty acids and water always produce negative effects, since the presence of free fatty acids and water causes soap formation, consumes catalyst, and reduces catalyst effectiveness, all of which result in a low conversion. These free fatty acids react with the alkaline catalyst to produce soaps that inhibit the separation of the biodiesel, glycerin, and wash water. To carry the base-catalyzed reaction to completion, a free fatty acid value lower than 3% is needed.

The presence of water has a greater negative effect on transesterification than that of the free fatty acids. In the transesterification of beef tallow catalyzed by sodium hydroxide (NaOH) in the presence of free fatty acids and water, the water and free fatty acid contents must be maintained at specified levels.

Transesterification can occur in different temperatures depending on the type of oil employed. The conversion rate increases with reaction time. The transesterification of rice bran oil with methanol was studied at molar ratios of 4:1, 5:1, and 6:1. At molar ratios of 4:1 and 5:1, there was significant increase in yield when the reaction time was increased from 4 to 6 h. Among the three molar ratios studied, ratio 6:1 gave the best results.

One of the most important factors that affect the yield of ester is the molar ratio of alcohol to triglyceride. Although the stoichiometric molar ratio of methanol to triglyceride for transesterification is 3:1, higher molar ratios are used to enhance the solubility and to increase the contact between the triglyceride and alcohol molecules. In addition, investigation of the effect of molar ratio on the transesterification of sunflower oil with methanol showed that when the molar ratio varied from 6:1 to 1:1 and concluded that 98% conversion to ester was obtained at a molar ratio of 6:1.

Another important variable affecting the yield of methyl ester is the type of alcohol to triglyceride. Short chain alcohols such as methanol, ethanol, propanol, and butanol can be used in the transesterification reaction to obtain high methyl ester yields.

Catalysts used for the transesterification of triglycerides are classified as alkali, acid, and enzyme. Alkali-catalyzed transesterification is much faster than acid-catalyzed transesterification and is most often used commercially, and, quite often, for the base-catalyzed transesterification, the best yields were obtained when the catalyst was used in a small concentration, i.e., 0.5% wt/wt of oil. On the other hand, data show that during the production of free and bound ethyl ester (FAEE) from castor oil, hydrochloric acid is much more effective than sodium hydroxide at higher reaction temperatures.

Supercritical Methanol Process

The transesterification of triglycerides by supercritical methanol (SCM), ethanol, propanol, and butanol has proved to be the most promising process. Recently, a catalyst-free method was developed for biodiesel production by

employing supercritical methanol. The supercritical treatment at 350°C (650°F) and approximately 6,000 psi with a molar ratio of 42 in methanol is the optimum condition for transesterification of oil from rapeseed to biodiesel fuel.

To achieve more moderate reaction conditions, further effort was made through the two-step preparation. In this method, oils/fats are, first, treated in subcritical water for hydrolysis reaction to produce fatty acids. After hydrolysis, the reaction mixture is separated into oil phase and water phase by decantation. The oil phase (upper portion) is mainly fatty acids, while the water phase (lower portion) contains glycerol in water. The separated oil phase is then mixed with methanol and treated at supercritical condition to produce FAME thorough methyl esterification. After removing unreacted methanol and water produced in reaction, FAME can be obtained as biodiesel. Therefore, in this process, methyl esterification is the main reaction for FAME formation, while in the one-step method, transesterification is the major one.

Reaction by supercritical methanol has some advantages which are (i) glycerides and free fatty acids are reacted with equivalent rates, (ii) the homogeneous phase eliminates diffusive problems, (iii) the process tolerates great percentages of water in the feedstock catalytic process require the periodical removal of water in the feedstock or in intermediate stage to prevent catalyst deactivation, (iv) the catalyst removal step is eliminated, and (v) if high methanol/oil ratios are used, total conversion of the oil to the product can be achieved in a few minutes.

Some disadvantages of the one-stage supercritical method are clear and are (i) the process operates at high pressures, (ii) the high temperatures used in the process require proportionally high heating and cooling costs, (iii) the high methanol/oil ratios which are typically set at 42 involve high costs for the evaporation of the unreacted methanol, and (iv) the process as proposed to date does not explain how to reduce free glycerol to less than 0.02% as established in a variety of international standards.

Transformation in the Environment

The major groups of pollutants and the principal reactions that can occur when the pollutants are released into the environment (degradation reactions or transformation reactions) require (i) the knowledge of the type of pollutants and (ii) the reactivity of the pollutants so that the design of the relevant method to remove the pollutants from the environment can be achieved. Although much emphasis has been, and continues to be, placed on biotic reactions carried out by the various biota (such as bacteria), important transformation reactions of the pollutants in the environment must not be omitted. Some of these chemical reactions will be beneficial – in terms of pollutant removal – while other chemical reactions may have adverse effects on pollutant removal by converting the pollutant to a product that is more capable of remaining in the environment and may even prove to be a persistent chemical. Thus, emphasis must be placed on the occurrence of partial degradation of pollutants and the role of the intermediate products that are toxic to floral and faunal organisms, inhibit further degradation, or have adverse effects on the environment. Thus, the chemical transformation of an chemical contaminant in the environment is an issue that needs to be given serious consideration because of the changes (often non-benign) that can occur to the chemical (Manzetti et al., 2014). It would be unusual if the chemical transformation did not show some effect on the properties of the discharged chemical.

The, chemical transformations of chemicals released into the environment are, in the context of this book, considered to be the transformation of the released chemical into a product that is still of concern in terms of toxicity. Furthermore, knowledge of the relative amounts of each species present is critical because of the potential for differences in behavior and toxicity (including the possibility of enhanced toxicity) which are of concern because of the potential fate of such chemicals.

As used here, the term *fate* refers to the ultimate disposition of the chemical in the ecosystem, either by chemical or biological transformation to a new form which (hopefully) is non-toxic (degradation) or, in the case of ultimately persistent pollutants, by conversion to less offensive chemicals or even by sequestration in a sediment or other location which is expected to remain undisturbed. Thus latter option – the sequestration in a sediment or other location – is not a viable option as for safety reasons, the chemical must be dealt with at some stage of its environmental life cycle and the chemical is likely to manifest its presence at some future date.

Furthermore, chemicals released into the environment are subject to two processes that determine the fate of the chemical in the environment: (i) the potential for transportation of the chemical and (ii) the chemical changes that can occur once the chemical has been released to the environment and which depend upon the chemical properties that can affect transportation processes and physical properties that can play a role in the transformation processes.

In the present context, when a chemical (or a mixture of chemicals) is released into the environment, the issues that need to be considered are (i) the toxicity of the chemical, (ii) the concentration of the released chemical, (iii) the concentration of the toxic chemical in the released material, (iv) the potential of the chemical to migrate to other sites, (v) the potential of the chemical to produce a toxic degradation product, whether or not the toxicity is lower or higher than the toxicity of the released chemical, (vi) the potential of the toxic degradation product or products to migrate to other sites, (vii) the persistence of the chemical in an ecosystem, (viii) the persistence of any toxic degradation product in an ecosystem, (ix) the potential for the toxic degradation product to degrade even further into harmful or non-harmful constituents and the rate of degradation, and (x) the degree to which the constituent or any degradation product of the constituent can accumulate in an ecosystem,

In order to complete such a list and monitor the behavior and effects of chemicals in an ecosystem, an understanding of chemical transformation processes in which a disposed or discharged chemical might particulate is valuable to any study of the effects on the environment. Chemical transformation processes change the chemical composition and structure of the discharged chemical which can change the properties (and possibly the toxicity) of the chemical and influence the behavior and life-cycle of the chemical in the environment.

As an example of chemical transformation of chemicals in the environment, weathering processes are ever-present and include such phenomena as (i) evaporation, (ii) leaching, which is transferred to the aqueous phase through dissolution, (iii) entrainment, which physical transport along with the aqueous phase, (iv) chemical oxidation, and (v) microbial degradation. The rate of transformation of the chemical is highly dependent on environmental conditions. For example, a product such a low-boiling naphtha solvent (boiling range 30 to 90°C, 86 to 194°F – a mixture of hydrocarbon derivatives produced from crude oil – will evaporate readily when spilled on to the surface of the Earth (specifically a water surface or land surface) and will give the appearance of a reception in the amount that remains. But the low-boiling constituents have not merely *disappeared* or *gone away* but have transferred from the land or from the water into the atmosphere. On the other hand, naphtha that has been inadvertently released into a formation that lies below a formation of clay minerals will tend to evaporate slowly (the clay can act as a formation trap) and may not be readily detectable.

However, the various chemical transformation processes, which influence the presence and the analysis of chemicals at a particular site, although often represented by simple (and convenient) chemical equations, can be complex (Neilson and Allard, 2012), and the true nature of the chemical transformation process is difficult to elucidate. The extent of transformation is dependent on many factors including (i) the properties of the chemical, (ii) the geology of the site, (iii) the climatic conditions, such as temperature, oxygen levels, and moisture, (iv) the type of microorganisms present, and (v) any other environmental conditions that can influence the life-cycle of the chemical. In fact, the primary factor controlling the extent of chemical transformation is the molecular composition of the chemical contaminant.

In the environment, a chemical transformation is the same principle as in the laboratory or in the chemical process industries – the transformation of a substrate to a product – but whether or not the product is benign and less likely to harm the environment (relative to the substrate) or is more detrimental by exerting having a greater impact on the environment depends upon the origin, properties, and reactivity pathways of the starting substrate. Thus, a chemical transformation requires a chemical reaction to lead to the transformation of one chemical to another (Neilson and Allard, 2012).

Transformation reactions may proceed in the forward direction and processed to completion as well as in the reverse direction until they reach equilibrium.

Thus,

Reactions that proceed in the forward direction to approach equilibrium are often described as spontaneous, requiring no input of free energy to go forward. Non-spontaneous reactions require input of free energy to go forward (examples application of heat for the reaction to proceed). In chemical synthesis, different chemical reactions are used in combinations during chemical synthesis in order to obtain a desired product. Also, in chemistry, a consecutive series of chemical reactions (where the product of one reaction is the reactant of the next reaction) are often catalyzed by a variety of catalysts which increase the rates of biochemical reactions, so that syntheses and decompositions impossible under ordinary conditions can occur at the temperatures, pressures, and reactant concentrations present within a reactor and, by inference, within the environment.

This simplified equation illustrates the potential complexity of chemical reaction, and such complexity must be anticipated when a chemical is transformed in an environmental ecosystem.

Thus, the focus is to develop a fundamental understanding of the nature of the chemical processes that occur when inorganic chemicals or organic chemicals are released into the environment. With this information, the activities that have an effect on the environment the chemistry can be estimated and even predicted.

Transuranium Elements

The transuranium elements (also known as transuranic elements) are the chemical elements with atomic numbers greater than 92, which is the atomic number of uranium (Table T-2). All of these elements are unstable and undergo radioactive decay into other elements.

Table T-2 The Periodic Table of the Elements.

1 H																	2 He				
3 Li	4 Be															5 B	6 C	7 N	8 O	9 F	10 Ne
11 Na	12 Mg															13 Al	14 Si	15 P	16 S	17 Cl	18 Ar

Of the elements with atomic numbers 1 to 92, most can be found in nature, having stable isotopes (such as hydrogen) or long-lived radioisotopes (such as uranium), or existing as common products of the decay of uranium and thorium (such as radon). The exceptions are elements 43, 61, 85, and 87 – all of which occur in nature.

Trace amounts of neptunium and plutonium form in some uranium-rich rock, and small amounts are produced during atmospheric tests of nuclear weapons. These two elements are generated from neutron capture ore with subsequent beta decay. Thus:

A beta particle has a small mass and is usually negatively charged. It is emitted from the nucleus of an atom with a charge of minus one. Beta radiation causes ionization by interfering with electrons in their orbits. Both have a negative charge, so the electrons are repelled when the beta particle passes.

All of the elements with a higher atomic number than plutonium (atomic number = 94) are synthetic insofar as they are created in nuclear reactors or particle accelerators. The half-life of each of these elements shows a general trend of decreasing as atomic number increases. There are exceptions, however, including several isotopes of curium (Cm, atomic number = 96) and dubium (Db, atomic number = 105). Some elements in this series (atomic numbers 110 to 114) are thought to break the trend and demonstrate increased nuclear stability, comprising the theoretical island of stability.

Traveling Grate Furnace

The traveling grate furnace is a type of furnace in which assembled links of grates are joined together in a perpetual belt arrangement and, thus, the traveling grate is a wide steel belt that carries the feedstock through the furnace. More specifically, the traveling grate is comprised of chain that carries the pellets like a conveyor. The difference is that the grate chain allows air to pass through it. The grate chain travels flat and straight, and in operation, fuel is fed in at one end and ash is discharged at the other.

While on the traveling grate, hot air is blown through the bed to dry and preheat the feedstock (usually pelletized) in preparation for being discharged into a rotary kiln. The pellets undergo an oxidation-reduction reaction in the kiln resulting in a change of chemistry and a hardened product suitable for transport to and use in blast furnaces.

The thickness of the bed in the traveling grate must remain consistent, despite fluctuations in the feed rate from upstream equipment, to maintain constant performance from the rotary kiln and maintain chemistry for the furnace.

See also: Combustion.

Tritium

Tritium (hydrogen-3) is the only radioactive isotope of hydrogen. The nucleus of a tritium atom consists of a proton and two neutrons. This contrasts with the nucleus of an ordinary hydrogen atom (which consists solely of a proton) and a deuterium atom (which consists of one proton and one neutron) (Table T-3).

Table T-3 The isotopes of hydrogen.

Isotope	Description
Protium	Ordinary hydrogen with one proton and one electron in the atom. When two atoms of protium are combined with one atom of oxygen, water is created.
Deuterium	Sometimes called "heavy hydrogen," a non-radioactive isotope that has a neutron in the atom, in addition to the proton and electron. Water made with this isotope is called "heavy water."
Tritium	A radioactive isotope of hydrogen that has two neutrons in addition to the proton and the electron. Water made with this isotope is called tritium oxide. Tritium is the only one of the three hydrogen isotopes that is radioactive.

Ordinary hydrogen comprises over 99.9% of all naturally occurring hydrogen. Deuterium comprises approximately 0.02%, and tritium comprises approximately a billionth of a billionth (10^{-18}) percent.

The most common forms of tritium are tritium gas (HT) and tritium oxide, also called “tritiated water.” In tritiated water, a tritium atom replaces one of the hydrogen atoms so the chemical form is HTO (hydrogen-tritium-oxygen) rather than H_2O (hydrogen-hydrogen-oxygen). The chemical properties of tritium are essentially the same as those of ordinary hydrogen. It decays with a half-life of 12 years by emitting a beta particle to produce helium-3. Tritium has a relatively high specific activity and is generated by both natural and artificial processes.

Tritium is naturally present as a small percentage of ordinary hydrogen in water, both liquid and vapor. This tritium is produced as a result of the interaction of cosmic radiation with gases in the upper atmosphere. After being produced in the atmosphere, tritium is readily incorporated into water and falls to earth as rain, thus entering the natural hydrological cycle.

Tritium is also produced as a fission product in nuclear weapons tests and in nuclear power reactors, with a yield of approximately 0.01%. That is, approximately one atom of tritium is produced per 10,000 fissions. Because little tritium is naturally present, it must be produced artificially for use on a practical scale. Tritium can be made in production nuclear reactors, i.e., reactors designed to optimize the generation of tritium and special nuclear materials such as plutonium-239. Tritium is produced by the neutron absorption of a lithium-6 atom. The lithium-6 atom, with three protons and three neutrons, and the absorbed neutron combine to form a lithium-7 atom with three protons and four neutrons, which instantaneously splits to form an atom of tritium (one proton and two neutrons) and an atom of helium-4 (two protons and two neutrons).

While tritium can also be produced in accelerators by bombarding helium-3 with neutrons, this approach has not been proven on a large scale. How is it used? Tritium is used as a component in nuclear weapons to boost the yield of both fission and thermonuclear (or fusion) warheads. Tritium is also used as a tracer in biological and environmental tritium (hydrogen-3).

The first generation of controlled fusion devices are being designed to liberate heat from the fusion of a deuteron (D) and a triton (T) to form an alpha particle, α , and a neutron, n, in the strongly exothermic nuclear reaction:

Radioactive tritium spontaneously decays to ^3He , an electron e^- and an electron antineutrino ($\bar{\nu}_e$) with a half-life of 12.3 years in the process of beta-decay:

The stable isotope ^3He , produced when tritium decays, has many uses already, for example, in neutron detectors, in ^3He - ^4He dilution refrigerators to produce millikelvin temperatures, and in magnetic-resonance imaging. Naturally occurring ^3He is so rare that virtually all of the current demand for ^3He is met with gas collected from the radioactive decay of tritium. In fact, tritium breeding is an essential component of potential future sources of electrical energy based on nuclear fusion.

Troposphere

The troposphere forms the bottom-most layer of the homosphere and is thus closest to the surface of the Earth – which is the layer of the atmosphere where life can exist without artificial life-support systems. It is also known as the weather layer of the Earth as it has all weather conditions. Airplanes fly at the very top of the troposphere, so they can fly over the weather, which causes turbulence. The jet stream, a fast-moving region of wind in the upper troposphere has been estimated to be on the order of 300 miles (or more) per hour. While temperatures at the bottom of the troposphere are nice and hospitable for life, temperatures at the top are approximately -50°C (-60°F). The troposphere is also the thinnest layer of the atmosphere and is approximately 10 miles high.

Thus, the troposphere is lowest layer of the atmosphere extending from sea level to an altitude of approximately 635 miles is the troposphere, which is characterized by a generally homogeneous composition of major gases other than water and decreasing temperature with increasing altitude from the heat-radiating surface of the land. The upper limit of the troposphere, which has a temperature minimum of approximately -56°C (-69°F), varies in altitude by a half mile (a kilometer) or so with atmospheric temperature, underlying terrestrial surface, and time. The homogeneous composition of the troposphere results from constant mixing by circulating air masses. However, the water vapor content of the troposphere is extremely variable because of cloud formation, precipitation, and evaporation of water from terrestrial water bodies. The boundary between the troposphere and the overlying stratosphere is known as the tropopause.

The troposphere contains the weather systems, air pollution, and the bulk of volcanic gases. The layer is characterized by air temperatures that decrease upward as distance increases from the warm surface of the Earth. Since the layer is defined by its thermal character, it would be expected to be thicker above warm regions and thinner over cold areas. In fact, the thickness of the troposphere increases from 5 miles over the polar regions of the Earth to as much as 10 miles at the equator.

Tumbling-Bed Gasifier

The tumbling bed gasifier is an apparatus in which the feedstock is lifted vertically in a revolving cylinder and dropped through an axially flowing stream of oxygen and steam.

See also: Gasification, gasifiers.

Turbine

A turbine is a rotary mechanical device that extracts energy from a fluid flow and converts the energy into useful work. The work produced by a turbine can be used for generating electrical power when combined with a generator. A turbine is a turbomachine with at least one moving part (a rotor assembly) which is a shaft or drum with blades attached. Moving fluid acts on the blades so that they move and impart rotational energy to the rotor. Early examples of turbines are windmills and waterwheels.

Gas, steam, and water turbines have a casing around the blades that contains and controls the working fluid. Modern steam turbines frequently employ both reaction and impulse in the same unit, typically varying the degree of reaction and impulse from the blade root to its periphery.

In practice, modern turbine designs use both reaction and impulse concepts to varying degrees whenever possible. Wind turbines use an airfoil to generate a reaction lift from the moving fluid and impart it to the rotor. Wind turbines also gain some energy from the impulse of the wind, by deflecting it at an angle. Turbines with multiple stages may use either reaction or impulse blading at high pressure. Steam turbines were traditionally more impulse but continue to move toward reaction designs similar to those used in gas turbines. At low pressure, the operating fluid medium expands in volume for small reductions in pressure. Under these conditions, blading becomes strictly a reaction-type design with the base of the blade solely impulse due to the effect of the rotation speed for each blade. As the volume increases, the blade height increases, and the base of the blade spins at a slower speed relative to the tip. This change in speed forces a designer to change from impulse at the base, to a high reaction-style tip.

See also: Steam Turbine.

Turbine - Condensing

The condensing turbine is able to use the total energy of the inlet steam flow to a maximum extent. Therefore, this type of turbine is used for power utilities that want to supply electricity to consumers as much as possible.

The last stages of a large condensing turbine operate in the wet steam region, where the steam contains 5 to 12% w/w water. Erosion of the turbine blades is initiated by a relatively small proportion of the water droplets in the steam separating out and collecting on the concave pressure face of the diaphragm blades, where a film is formed which is drawn toward the trailing edge by the drag of the steam. Here, the film grows and passes around the trailing edge on to the convex face where, usually in a region of strong secondary flow, droplets move back and forth increasing in size until they are torn away by the shearing action of the main flow of steam. Relatively large drops (50-200 μm in diameter) are produced and have to be accelerated from rest by the steam. These large drops arrive at the inlet plane of the moving blade row at only a fraction of the absolute velocity of the steam and are subsequently struck by the convex surfaces of the moving blade row.

The condensing turbine has heat discharge loss because all exhaust steam flow is condensed in the condenser that is cooled by cooling water, which means that a lot of discharged heat is thrown away outside. Furthermore, the condensing turbine consists of many turbine stages and large steam flow in the low pressure turbine; as a result, the low pressure turbine will become larger.

See also: Horizontal and Vertical Axis Turbine, Turbine.

Turbine – Horizontal and Vertical Axis

Both horizontal and vertical axis turbines are applicable to applications such as tidal currents or river streams and are perceived as a critical element to hydrokinetic conversion concepts. Hydrokinetic energy conversion may employ either rotary turbo machinery or can use non-turbine schemes. While the former class (turbine system) encompasses various classical rotary technologies, the latter group (non-turbine system) is mostly based on various unconventional concepts. Such schemes include oscillating hydrofoil [30], vortex- induced vibration, piezo polymer conversion, and variable geometry sails.

See also: Horizontal and Vertical Axis Turbine, Turbine.

Turbine – Impulse

Impulse turbines or turbine stages are simple, single-rotor or multirotor (compounded) turbines to which impulse blades are attached. Impulse blades can be recognized by their shape. Because they are usually used in the entrance high-pressure stages of a steam turbine, when the specific volume of steam is low and requires much smaller flow areas than at lower pressures, the impulse blades are short and have constant cross sections. Impulse turbines are also characterized by the fact that most or all of the enthalpy and hence the pressure drop occurs in the nozzles (or fixed blades that act as nozzles) and little or none in the moving blades.

An impulse turbine changes the direction of flow of a high velocity fluid or gas jet. The resulting impulse spins the turbine and leaves the fluid flow with diminished kinetic energy. There is no pressure change of the fluid or gas in the turbine blades (the moving blades), as in the case of a steam or gas turbine; all the pressure drop takes place in the stationary blades (the nozzles). Before reaching the turbine, the pressure head of the fluid is changed to velocity head by accelerating the fluid with a nozzle. Pelton wheels and de Laval turbines use this process exclusively. Impulse turbines do not require a pressure casing around the rotor since the fluid jet is created by the nozzle prior to reaching the blades on the rotor. Newton's second law describes the transfer of energy for impulse turbines. Impulse turbines are most efficient for use in cases where the flow is low and the inlet pressure is high.

See also: Turbine.

Turbine – Reaction

A reaction turbine develops torque by reacting to the gas or fluid's pressure or mass. The pressure of the gas or fluid changes as it passes through the turbine rotor blades. A pressure casing is needed to contain the working fluid as it acts on the turbine stage(s), or the turbine must be fully immersed in the fluid flow (such as with wind turbines).

The casing contains and directs the working fluid and, for water turbines, maintains the suction imparted by the draft tube. A Francis turbine and most steam turbines use this concept. For compressible working fluids, multiple turbine stages are usually used to harness the expanding gas efficiently. Newton's third law describes the transfer of energy for reaction turbines. Reaction turbines are better suited to higher flow velocities or applications where the fluid head (upstream pressure) is low.

See also: Turbine.

Turbine – Steam

The steam turbine is a device that extracts thermal energy from pressurized steam and uses it to do mechanical work on a rotating output shaft. It is a form of heat engine that derives much of its improvement in thermodynamic efficiency from the use of multiple stages in the expansion of the steam, which results in a closer approach to the ideal reversible expansion process. Because the turbine generates rotary motion, it is particularly suited to be used to drive an electrical generator.

In the case of steam turbines, such as would be used for marine applications or for land-based electricity generation, a Parsons-type reaction turbine would require approximately double the number of blade rows as a de Laval-type impulse turbine, for the same degree of thermal energy conversion. While this makes the Parsons turbine much longer and heavier, the overall efficiency of a reaction turbine is slightly higher than the equivalent impulse turbine for the same thermal energy conversion.

See also: Electricity Generation – Equipment, Steam Turbine.

Turbopause

The turbopause (also known as the homopause) marks the altitude in an atmosphere below which turbulent mixing dominates. The region below the turbopause (the homosphere) is the region in which the atmosphere is well mixed for chemical species which have long mean residence times. Highly reactive chemicals tend to have variable concentration throughout the atmosphere, while unreactive species have more homogeneous concentrations. The region above the turbopause is the heterosphere, where molecular diffusion dominates and the chemical composition of the atmosphere varies according to chemical species and their atomic weight.

Turbulence plays an important role through much of the atmosphere of the Earth. Below a height of approximately 65 miles, turbulence mixes the various species of gas that make up the atmosphere. As a result of this mixing, the major gases are found in approximately the same proportion just below 60 miles as they are at the ground. This region is called the heterosphere. The boundary below which there is mixing of all species, the homopause, is in fact somewhat lower than the turbopause, the height above which no turbulence occurs. This difference in altitude exists because less turbulence occurs in the highest parts of the turbulent region and mixing is not as complete. The turbopause itself exists because it represents the lower boundary of a region in which molecular viscosity and ion drag damp vertical gradients to such an extent that the small structures associated with turbulence are not formed. Thus, there is no process that mixes the gas and maintains the same composition throughout the rest of the thermosphere. Instead, the density of each species decreases with altitude above the turbopause at a rate that is related to the mass of the species.

See also: Atmosphere.

Two-Stage Gasification

The two-stage gasification process is a process in which partial gasification or pyrolysis is the first step followed by complete gasification of the resultant char in a second step.

The major methods of biomass thermal conversion are (i) combustion in excess oxygen, (ii) gasification in reduced oxygen, and (iii) pyrolysis in the absence of oxygen, and the end products of these methods are heat, gas, liquid, and solid fuels. However, in terms of energy production, these methods are not always optimal.

A two-stage thermal conversion of biomass based on pyrolysis as the first stage and pyrolysis products cracking as the second stage can be considered the optimal method for energy production that allows obtaining synthesis gas consisting of hydrogen and carbon monoxide and not containing liquid or solid particles.

The E-Gas process features a two-stage gasifier design in which the gasifier is refractory-lined and uses coal-water slurry feed. The first stage of the gasifier has two opposed, horizontally oriented feed injectors. The synthesis gas exits the top of the first stage, and slag flows out of the bottom into a water bath. The synthesis gas produced by the first stage enters the second stage at temperatures comparable to the exit temperatures of the other two entrained flow gasifiers. Additional coal-water slurry is injected into this hot syngas in the second gasifier stage, but no additional oxygen is injected. Endothermic gasification reactions occur between the hot syngas and the second stage coal feed. This lowers the temperature of the syngas and increases the cold gas efficiency of the process. Upon exiting the top of the second stage of the gasifier, the syngas passes through a syngas cooler which features a firetube design. The cooled syngas then enters a rigid barrier filter where any unconverted char from the second stage is collected and recycled back to the first stage of the gasifier where the hotter temperatures ensure near complete carbon conversion.

The advantage of the two-stage process in comparison with air gasification is the high calorific value of gas produced due to the absence of nonflammable nitrogen in its composition. Another advantage of the process is the relatively low cost in comparison with other gasification methods, such as oxygen or steam gasification.

See also: E-Gas Process.

U-Gas Process

The U-Gas process was developed to produce gaseous product from coal in an efficient and environmentally acceptable manner. The product gas may be used to produce low-Btu gas, medium-Btu gas, and synthetic natural gas (SNG) for use as fuels, or as chemical feedstocks for the production of ammonia, methanol, hydrogen, and oxo-chemicals, or for electricity generation. The process is capable of handling large volumes of gas throughput, achieving a high conversion of coal to gas without producing tar or oil, and causing minimum damage to the environment. The process is based on a single-stage, fluidized bed gasifier which accomplishes four principal functions in a single stage, which are (i) decaking coal, (ii) devolatilizing coal, (iii) gasifying coal, and (iv) agglomerating and separating ash from char.

In the process, coal of approximately 0.25-inch diameter is dried and pneumatically injected into the gasifier through a lock hopper system. In the fluidized bed reactor, coal reacts with steam and oxygen at a temperature of 950 to 1,100°C (1,740 to 2,010°F). The temperature of the bed is determined based on the type of coal feed and is controlled to prevent slagging conditions of ash. The pressure typically ranges from 50 to 350 psi, and is largely determined based on the ultimate use of the final product gas. Oxygen may be substituted with air.

In the gasifier, coal is rapidly gasified producing hydrogen (H_2), carbon monoxide (CO), carbon dioxide (CO_2), and small amounts of methane (CH_4). The fluidized bed is always maintained under reducing conditions, and, as such, all sulfur species present in coal is converted into hydrogen sulfide (H_2S). During the process, the ash is agglomerated into spherical particles that grow in size and are separated from the bed into water-filled ash hoppers, from which they are withdrawn as slurry. A portion of fluidizing gas enters the gasifier section through an inclined grid, whereas most of the remaining entering gas flows upward at a high velocity through the ash-agglomerating zone and forms a relatively hot zone within the bed.

Coal fines elutriated from the bed are collected by two external cyclones – the fines from the first cyclone are returned to the bed, whereas the fines from the second cyclone are sent to the ash-agglomerating zone. Raw product gas is virtually free of tar and oils, thus simplifying the ensuing energy recovery and gas purification steps.

See also: Gasification.

Ultrafiltration and Microfiltration

The ultrafiltration process and the microfiltration process are pressure-driven filtration processes in which the smaller pores of the ultrafiltration membranes make the retention of large dissolved species (typically with a molecular weight greater than 500) along with retention of any particulate matter. Thus, the distinction between ultrafiltration and microfiltration is made on the basis of the size of the materials screened out by the membrane and thus on the apparent size of the holes in the membrane.

The range of pore sizes described for ultrafiltration membranes is typically on the order of 20 to 1,000 Å, while microfiltration membranes have pores in the range of 1,000 to 100,000 Å (0.1 to 10 microns). These pore size ranges describe what is meant by ultrafiltration and microfiltration membranes.

The membranes for microfiltration can be either of two main types having different pore structures. One type consists of a relatively thick spongy structure of polymer much like the support layer of a reverse osmosis membrane. It has tortuous pores through the membrane with a relatively wide size distribution. Furthermore, the pore diameter can vary along the pore length. Thus, plugging of the pores can be a problem if the pores are too close to the size of the particles to be rejected. The other type of membrane has a narrow size distribution of straight-through pores. It is usually much thinner than the spongy membrane.

Because of the higher molecular weights of the solutes removed by ultrafiltration as compared to reverse osmosis, osmotic pressure is low enough not to be a consideration. Generally, pressure gradients as low as 5 to 100 psig across the membrane are sufficient to achieve satisfactory flux rates. Furthermore, the larger pore size in ultrafiltration membranes can lead to passage of ionic materials and small molecules, while retaining larger dissolved organic species. These retained substances may be insoluble particulate matter such as complexed heavy metals and other suspended solids.

See also: Membrane Permeation, Membrane Processes.

Unconventional Gas

Unconventional gas is gas that occurs in tight sandstones, siltstones, sandy carbonates, limestone, dolomite, and chalk. The boundary between conventional gas and unconventional gas resources is not well defined, because they result from a continuum of geologic conditions. Coal seam gas, more frequently called coal bed methane, is frequently referred to as unconventional gas. Tight shale gas and gas hydrates are also placed into the category of unconventional gas.

One form of unconventional gas is coal bed methane (CBM) which is the generic term given to methane gas held in underground coal seams and released or produced when the water pressure within the seam is reduced by pumping from either vertical or inclined to horizontal surface holes. The methane is predominantly formed during the coalification process whereby organic matter is slowly transformed into coal by increasing temperature and pressure as the organic matter is buried deeper and deeper by additional deposits of organic and inorganic matter over long periods of geological time. This is referred to as thermogenic coal bed methane.

Shale gas is another form of unconventional gas, and large continuous gas accumulations are sometimes present in low permeability shale, (tight) sandstones, siltstones, sandy carbonates, limestone, dolomite, and chalk. Such gas deposits are commonly classified as unconventional because their reservoir characteristics differ from conventional reservoirs and they require stimulation to be produced economically.

Gas hydrates are another form of unconventional gas and are molecules consisting of an ice lattice or cage in which low-molecular-weight hydrocarbon derivatives, such as methane, are embedded. The two major conditions that promote hydrate formation are: (1) high gas pressure and low gas temperature and (2) the gas at or below its water dew point with free water present.

Gas hydrates are common constituents of the shallow marine geosphere and occur both in deep sedimentary structures, and as outcrops on the ocean floor. Methane hydrates are believed to form by migration of gas from depth along geological faults, followed by precipitation, or crystallization, on contact of the rising gas stream with cold sea water. At high pressures, methane hydrates remain stable at temperatures up to 18°C and the typical methane hydrate contains one molecule of methane for every 6 molecules of water that forms the ice cage, but this ratio is dependent on the number of methane molecules that fit into the various cage structures of the water lattice. One liter of solid methane hydrate can contain up to 168 liters of methane gas.

Undiscovered Reserves

One major issue in the estimation of coal (or for that matter any fossil fuel or mineral) resource is the all-too-frequent use of the term *undiscovered resources* (Table U-1). Often, the data provided to substantiate such reserves are very speculative and open to questions related to the degree of certainty. There are three important items that counteract the guesswork applied to *undiscovered* resources: (i) the actual discoveries of new coal reserves, (ii) the development of improved mining technologies for already known coal reserves, and (iii) estimates of the coal resource base that are derived from known resource properties where the whole of the resource is not explored.

Table U-1 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

The total resource base of any fossil fuel (or, for that matter, of any mineral resource) will be dictated by economics. When coal resource data are quoted, some attention must be given to the cost of recovering those reserves. Most importantly, the economics must also include a cost factor that reflects the willingness to secure total, or a specific degree of, energy independence, including some serious consideration of the very real environmental aspects of coal use.

See also: Reserves.

Unit Process

A unit process (sometimes referred to as a unit operation) is a basic physical operation in a processing sequence. Examples are distillation, absorption, fluid flow, as well as heat and mass transfer. Fundamentals pertaining to a given unit operation are the same regardless of the industrial applications. Examples are: (i) fluid flow, which deals with the principles governing the flow and transportation of fluids, (ii) heat transfer, which deals with the principles underlying the heat transfer by different methods, and (iii) distillation, absorption, extraction, and drying – which are also referred to as diffusional mass transfer unit operations – in which the separation of natural gas and crude oil hydrocarbons is accomplished by the transfer of molecules from one phase to the other by diffusion.

The significance of introducing the unit operation concept in understanding the processing surface operations in a natural gas field or an oil field is apparent to readers when it is realized that most of these surface operations are *physical operations processes* or *non-reacting processes*. The processes focus on the transfer and the transformation of *energy*, and the transfer, separation, and conditioning (treating) of *materials* by physical means.

Three modes of transfer that take place in oil field processing operations are recognized as follows: (i) momentum transfer, which is achieved by fluid flow, (ii) heat transfer of crude oil and crude oil products using heat exchangers and furnaces, and (iii) mass transfer in distillation columns, absorbers, and others that lead to enrichment and separation in which the transfer is due to the diffusion of the molecular constituents that separates the low-boiling constituents from the higher boiling constituents.

See also: Refining.

Unisol Process

The Unisol process is a regenerative chemical process for extracting mercaptan sulfur and certain nitrogen compounds from sour gasoline or distillates using regenerable aqueous solutions of sodium hydroxide or potassium hydroxide containing methanol.

More specifically, the process is a regenerative method for extracting not only mercaptan derivatives (RSH) but also certain nitrogen compounds from sour (sulfur-containing) distillates. The distillate (such as naphtha or gasoline), free of hydrogen sulfide, is washed countercurrently with aqueous caustic-methanol solution at approximately 40°C (104°F). The spent caustic is regenerated in a stripping tower (145 to 150°C, 290 to 300°F), where methanol, water, and mercaptans are removed.

Unit Collector

A unit collector, unlike a central collector, controls contamination at its source. It is small and self-contained, consisting of a fan and some form of dust collector. A unit collector is suitable for isolated, portable, or frequently moved particulate-producing (dust-producing) operations, such as bins and silos or remote belt-conveyor transfer points. The advantages of unit collectors include (i) small space requirements, (ii) the return of collected particulate matter (or dust) to main material flow, and low initial cost.

The collector is used to enhance the quality of air released from industrial and commercial processes by collecting particulate matter, dust, and other impurities from air or gas. Designed to handle high-volume loads, a collector system consists of a blower, filter, a filter-cleaning system, and a particle receptacle or particle removal system.

A number of designs are available, with capacities ranging from 200 to 2,000 ft³/min (90 to 900 L/s). There are two main types of unit collectors: (i) fabric collectors, with manual shaking or pulse-jet cleaning – normally used for fine particulate matter and dust, and (ii) cyclone collectors – normally used for coarse particulate matter and dust. Fabric collectors are frequently used in minerals processing operations because they provide high collection efficiency and uninterrupted exhaust airflow between cleaning cycles. On the other hand, cyclone collectors are used when coarser material is generated, as in woodworking, metal grinding, or machining.

See also: Centrifuge, Cyclone, Fabric Filters.

Unproven Reserves

Unproven reserves (unproved reserves) are based on geologic and/or engineering data similar to that used in estimates of proved reserves, but technical, contractual, economic, or regulatory uncertainties preclude such reserves being classified as proved (Table U-2).

Table U-2 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

In many countries, unproven reserves (due to regulatory factors or economic factors) are estimated as less recoverable and therefore unproven. This class of reserves is further broken down into subcategories of probable and possible.

See also: Resources and Reserves.

Unsaturated Hydrocarbons

The presence of olefins ($R^1CH=CHR^2$, where R^1 and R^2 can be the same or different groups) in petroleum has been under dispute for many years because there are investigators who claim that olefins are actually present. In fact, these claims usually refer to distilled fractions, and it is difficult to entirely avoid cracking during the distillation process. Nevertheless, evidence for the presence of considerable proportions of olefins in Pennsylvanian crude oils has been obtained; spectroscopic and chemical methods showed that the crude oils, as well as all distillate fractions, contained up to 3% w/w olefins. Hence, although the opinion that petroleum does not contain olefins requires some revision, it is perhaps reasonable to assume that the Pennsylvania crude oils may hold an exceptional position and that olefins are present in crude oil in only a few special cases. The presence of dienes ($RCH=CH-CH=R'$) and acetylenes ($RC\equiv CR'$) is considered to be extremely unlikely.

In summary, a variety of hydrocarbon compounds occur throughout petroleum. Although the amount of any particular hydrocarbon varies from one crude oil to another, the family from which that hydrocarbon arises is well represented.

See also: Olefin Hydrocarbons.

Updraft Combustion

Updraft combustion involves lumps of coal in a bed supported by a grate, and provision is made for the supply of primary air beneath the bed and secondary air above it as there is a connection to a flue in order to provide a draught. A fire of this type is ignited at the base, after which the flame front then spreads upward until the whole bed is incandescent. The best-known example of coal combustion is provided by the domestic fire which operates on the same over-feed principle.

See also: Combustion.

Updraft Gasifier

The simplest type of gasifier is the updraft gasifier (fixed bed countercurrent gasifier). The biomass is fed at the top of the reactor and moves downwards as a result of the conversion of the biomass and the removal of ashes. The air intake is at the bottom and the gas leaves at the top. The biomass moves in countercurrent to the gas flow, and passes through the drying zone, the distillation zone, reduction zone, and the oxidation zone.

The countercurrent fixed bed (up draft) gasifier consists of a fixed bed of carbonaceous fuel (e.g., coal or biomass) through which the "gasification agent" (steam, oxygen and/or air) flows in countercurrent configuration. The ash is either removed dry or as a slag. The slagging gasifiers require a higher ratio of steam and oxygen to carbon in order to reach temperatures higher than the ash fusion temperature. The nature of the gasifier means that the fuel must have high mechanical strength and must be non-caking so that it will form a permeable bed, although recent developments have reduced these restrictions to some extent. The throughput for this type of gasifier is relatively low. Thermal efficiency is high as the gas exit temperatures are relatively low. However, this means that tar and methane production is significant at typical operation temperatures, so the product gas must be extensively cleaned before use or recycled to the reactor.

The major advantages of this type of gasifier are its simplicity, high charcoal burn-out, and internal heat exchange leading to low gas exit temperatures and high gasification efficiency. In this way, fuels with high moisture content (up to 50% w/w) can also be used.

Major drawbacks are the high amounts of tar and pyrolysis products because the pyrolysis gas is not led through the oxidation zone. This is of minor importance if the gas is used for direct heat applications, in which the tar product is burned. In case the gas is used for engines, gas cleaning is required, resulting in problems of tar-containing condensates.

Upflow Expanded-Bed Reactor

Expanded-bed reactors are applicable to distillates, but are commercially used for very heavy, high metals, and/or dirty feedstocks having extraneous fine solids material. They operate in such a way that the catalyst is in an expanded state so that the extraneous solids pass through the catalyst bed without plugging. They are isothermal, which conveniently handles the high-temperature exotherm associated with high hydrogen consumptions. Since the catalyst is in an expanded state of motion, it is possible to treat the catalyst as a fluid and to withdraw and add the catalyst during operation.

Expanded beds of catalyst are referred to as particulate fluidized insofar as the feedstock and hydrogen flow upward through an expanded bed of catalyst with each catalyst particle in independent motion. Thus, the catalyst migrates throughout the entire reactor bed. Expanded-bed reactors are mathematically modeled as back-mix reactors with the entire catalyst bed at one uniform temperature. Spent catalyst may be withdrawn and replaced with fresh catalyst on a daily basis. Daily catalyst addition and withdrawal eliminate the need for costly shutdowns to change out catalyst and also result in a constant equilibrium catalyst activity and product quality. The catalyst is withdrawn daily and has vanadium, nickel, and carbon content that is representative on a macro-scale of what is found throughout the entire reactor. On a micro-scale, individual catalyst particles have ages from that of fresh catalyst to as old as the initial catalyst charge to the unit, but the catalyst particles of each age group are so well dispersed in the reactor that the reactor contents appear uniform.

In the unit, the feedstock and hydrogen recycle gas enter the bottom of the reactor, pass up through the expanded catalyst bed, and leave from the top of the reactor. Commercial expanded-bed reactors normally operate with 1/32 inch (0.8 mm) extrudate catalysts that provide a higher rate of desulfurization than the larger catalyst particles used in fixed-bed reactors. With extrudate catalysts of this size, the upward liquid velocity based on fresh feedstock is not sufficient to keep the catalyst particles in an expanded state. Therefore, for each part of the fresh feed, several parts of product oil are taken from the top of the reactor, recycled internally through a large vertical pipe to the bottom of the reactor, and pumped back up through the expanded catalyst bed. The amount of catalyst bed expansion is controlled by the recycle of product oil back up through the catalyst bed.

The expansion and turbulence of gas and oil passing upward through the expanded catalyst bed are sufficient to cause almost complete random motion in the bed (particulate fluidized). This effect produces the isothermal operation. It also causes almost complete back-mixing. Consequently, in order to effect near complete sulfur removal (over 75%), it is necessary to operate with two or more reactors in series. The ability to operate at a single temperature throughout the reactor or reactors, and to operate at a selected optimum temperature rather than an increasing temperature from the start to the end of the run, results in more effective use of the reactor and catalyst contents. Use of a smaller catalyst particle size, isothermal, fixed temperature throughout run, back-mixing, daily catalyst addition, and constant product quality, the reactor size required for an expanded bed is often smaller than that required for a fixed bed to achieve the same product goals.

Upper Explosive Limit

Before a fire or explosion can occur, three conditions must be met simultaneously and are (i) a fuel, such as a combustible gas, (ii) oxygen or air must exist in certain proportions, and (iii) an ignition source, such as a spark or flame. The ratio of fuel and oxygen that is required varies with each combustible gas or vapor (Table U-3).

Table U-3 Examples of the lower and upper explosive limits of selected chemicals in air.

Chemical	LEL	UEL
1,3-Butadiene	2.0	12.0
1-Butene	1.6	10.0
Benzene	1.3	7.9
Butane	1.8	8.4
Carbon Monoxide	12.5	74.0
Carbonyl Sulfide	12.0	29.0
Cyclohexane	1.3	7.8
Cyclopropane	2.4	10.4
Dimethyl Ether	3.4	27.0
Ethane	3.0	12.4
Ethanol	3.3	19.0
Ethylene	2.7	36.0
Heptane	1.1	6.7
Hexane	1.2	7.4
Hydrogen	4.0	75.0
Hydrogen sulfide	4.0	44.0
Isobutane	1.8	8.4
Isobutylene	1.8	9.6
Methane	5.0	15.0
Methanol	6.7	36.0
Methyl mercaptan	3.9	21.8
Propylene	2.4	11.0
Toluene	1.2	7.1
Xylene	1.1	6.6

The minimum concentration of a particular combustible gas or vapor necessary to support its combustion in air is the lower explosive limit (LEL) for that gas. Below this level, the mixture is too “lean” to burn. The maximum concentration of a gas or vapor that will burn in air is defined as the upper explosive limit (UEL). Above this level, the mixture is too “rich” to burn. The range between the lower explosive limit and the upper explosive limit is known as the flammable range for that gas or vapor.

See also: Explosive Limits, Lower Explosive Limit, Lower Flammability Limit Upper Flammability Limit.

Upper Flammability Limit

The upper flammability limit is the maximum concentration by volume of a combustible substance that is capable of continued propagation of a flame under the specified conditions.

Controlling gas and vapor concentrations outside the flammable limits is a major consideration in fuel technology. The methods used to control the concentration of a potentially explosive gas or vapor include the use of sweep gas, an unreactive gas such as nitrogen to dilute the explosive gas before coming in contact with air. The use of scrubbers or adsorption resins to remove explosive gases before release is also common. Gases can also be maintained safely at concentrations above the upper explosive limit, although a breach in the storage container can lead to explosive conditions or intense fires.

Dusts also have upper and lower explosion limits. Flammability limits also depend on the particle size of the dust involved, and are not intrinsic properties of the material. In addition, a concentration above the lower explosive limit can be created suddenly from settled dust accumulations. The preferred method of managing combustible dust is by preventing accumulations of settled dust through process enclosure, ventilation, and surface cleaning.

Situations caused by evaporation of flammable liquids into the air-filled void volume of a container may be limited by flexible container volume or by using an immiscible fluid to fill the void volume.

See also: Gas Cleaning, Lower Explosive Limit, Lower Flammability Limit.

Uranium

Uranium is a chemical element (symbol U, atomic number = 92) which is a silvery-gray metal in the actinide series of the Periodic Table. A uranium atom has 92 protons and 92 electrons of which six of the electrons are valence electrons. Uranium is radioactive because all of the isotopes of uranium are unstable – the half-lives of the naturally occurring isotopes range from 159,200 years to 4.5 billion (4.5×10^9) years. The most common isotopes in natural uranium are uranium-238 (^{238}U) which has 146 neutrons and accounts for more than 99% of uranium on Earth and uranium-235 (^{235}U) which has 143 neutrons.

The many uses of uranium exploit its unique nuclear properties. For example, uranium-235 (^{235}U) is the only naturally occurring fissile isotope and is used widely in nuclear power plants and nuclear weapons. However, because of the small amounts found in nature, uranium needs to undergo enrichment so that enough uranium-235 (^{235}U) is present in the enriched product. Uranium-238 (^{238}U) is fissionable by fast neutrons and can be transmuted to fissile plutonium in a nuclear reactor. Another fissile isotope, uranium-233 (^{233}U), can be produced from natural thorium.

Urban Waste

Urban waste (municipal waste) is the waste generated by cities and municipalities and the associated landfills and is the largest source of human-related methane in the United States, accounting for 34% of these emissions. Methane is a potent greenhouse gas that contributes to smog and to the global warming of the atmosphere, remaining in the atmosphere for 9-15 years. When burned under controlled conditions rather than letting it escape into the atmosphere, methane becomes a valuable renewable energy resource that can generate electricity, heat, or fuel for vehicles.

Turning hazardous landfill gas into marketable energy adds to landfill safety, improves the environment, and decreases odors. Purified methane can be used on the premises for electricity or to fuel boilers or other thermal applications. Pipeline grade methane can be transported by pipeline for sale to the local power grid to run electric generators.

See also: Landfill, Landfill Gas, Municipal Solid Waste, Waste.

Urban Waste Briquettes

Solid waste disposal is one of the most serious urban environmental problems in developing countries. Many municipal authorities collect and adequately dispose (in places other than landfill sites) less than half of these wastes. This failure is attributed to (1) an inadequate number of landfill sites, (2) a variety of environmental regulations, (3) the absence of sufficient capacity for waste processing and recycling, and last, but not least, (4) the planned obsolescence of packaging and many of the items that form the basis of the waste.

Open or crude dumping is the most common method used by municipal authorities. Waste poses a health hazard when it lies scattered in the streets and at the dumping sites. It is now an accepted environmental philosophy that wastes have value and should be utilized based on principles of reduce, reuse, recover, and recycle. Through recycling, urban wastes can be transformed into useful products. Waste paper and leaves, in particular, provide a potentially important, alternative source of cooking fuel.

See also: Bagasse Briquettes, Briquetting, Urban Waste.

Vapor Density

The vapor density is an important property of gases and low-boiling liquids. Once gases (and low-boiling liquids) are produced under the landfill surface, they generally move away from the landfill. These products, especially the gases, tend to expand and fill the available space, so that they move or *migrate* through the limited pore spaces within the refuse and soils covering of the landfill. The tendency of some landfill gases, such as methane, that is less dense than air, is to move upward, usually through the landfill surface. However, of the hydrocarbon derivatives, methane is the only one that is less dense than air. Higher-molecular-weight hydrocarbon derivatives such as ethane, propane, and butane are denser than air (Table V-1) and may collect in pockets rather than migrate with the methane. In addition, the methane may have a pronounced solubility in the hydrocarbon liquids.

Table V-1 Density and vapor density of the lower-boiling hydrocarbon derivatives.

Hydrocarbon	Molecular weight	Specific gravity	Vapor density, air = 1
Methane	16	0.553	0.56
Ethane	30	0.572	1.04
Propane	44	0.504	1.50
Butane	58	0.601	2.11
Pentane	72	0.626	2.48
Hexane	86	0.659	3.00

The pockets of gas that do not move out of the landfill can cause safety issues when the pockets are suddenly opened to the air (for example, during landfill mining) and the flammability limit or flash point of the collected gas is reached.

Using landfill gas as the example, a major concern is the possibility of the gas accumulation inside buildings constructed on or close to a landfill site and forming pockets of gas around the building or inside the building. Protection of buildings is usually achieved using a dual barrier approach: low permeability gas membrane to resist the passage of gas, and some form of ventilation/extraction system to disperse the gas safely to the atmosphere. The requirements for particular developments will be specified by the relevant planning authorities. Gas monitoring may also be a requirement and, if so, it indicates that gas detectors must be installed at the most effective location.

In an industrial setting, the vapor density may be derived from a composition of the gas or liquid density with hydrogen rather than air.

Vapor Pressure

The *vapor pressure* is the force exerted on the walls of a closed container by the vaporized portion of a liquid. Conversely, it is the force that must be exerted on the liquid to prevent it from vaporizing further (ASTM D323). The vapor pressure increases with temperature for any given gasoline, liquefied petroleum gas, or other products. The temperature at which the vapor pressure of a liquid, either a pure compound or a mixture of many compounds, equals 1 atmosphere (14.7 psi, absolute) is designated as the boiling point of the liquid.

The vapor pressure of a chemical provides an indication of its volatility at any specific temperature. As an approximation, the vapor pressure p of a pure chemical is given by the equation:

$$\log_e p = (A/T) + B$$

A and B are empirically determined constants, and T is the absolute temperature. Hence, the vapor pressure of a chemical will increase markedly with temperature.

For a component 'a' in a mixture of vapors, its partial pressure p_a is the pressure that would be exerted by that component at the same temperature if present alone in the same volumetric concentration. So, with a mixture of two components, 'a' and 'b', the total pressure is:

$$P = p_a + p_b$$

If an inert gas is also present, its pressure is additive:

$$P = p_a + p_b + p_{\text{inert}}$$

In an 'ideal mixture', the partial pressure p_a is proportional to the mole fraction y_a of the component in the gas phase:

$$p_a = y_a P$$

This partial pressure is also related to the concentration in the liquid phase expressed as mole fraction x_a by:

$$p_a = p_a^* x_a$$

In this equation, p_a^* is the vapor pressure of component 'a' at the prevailing temperature. So, if all of the components are miscible in the liquid phase, the total pressure P of a mixture is:

$$P = p_a^* x_a + p_b^* x_b + p_c^* x_c$$

As a result: (i) the flash point of any flammable liquid will be lowered if it is contaminated with a more volatile, flammable liquid, (ii) application of heat to a flammable liquid (e.g., due to radiation or flame impingement in a fire, or because of 'hot work') can generate a flammable vapor-air mixture, (iii) an increase in temperature of a toxic liquid can create an excessive concentration of toxic vapor in air which may occur as the result of an exothermic reaction, (iv) the pressure in the vapor space of an incompletely full, sealed vessel containing liquid cannot be reduced by partially draining off liquid, (v) the pressure in an incompletely full container of liquid will increase with temperature and can, in the extreme, result in rupture due to over-pressurization unless adequate relief is provided (which may occur following an uncontrolled exothermic reaction) or, alternatively, partial ejection of the contents can occur on opening, and (vi) the composition of the vapor in equilibrium with a miscible liquid mixture at any temperature, e.g., on heating during distillation, will be enriched by the more volatile components – the composition of the liquid phase produced on partial condensation will be enriched by the less volatile components, and such *fractionation* can have implications for safety in that the flammability and relative toxicity of the mixtures can change significantly.

Vegetable Oils

Vegetable oils (Table V-2) are obtained from seed oil plants such as palm, sunflower, and soya. The predominant source of vegetable oils in many countries is rapeseed oil. Vegetable oils are a major feedstock for the oleo-chemicals industry (surfactants, dispersants, and personal care products) and are now successfully entering new markets such as diesel fuel, lubricants, polyurethane monomers, functional polymer additives, and solvents.

Table V-2 Fatty acid content of some vegetable oils (%)

Vegetable Oil	Palmitic 16:0	Stearic 18:0	Palmitoleic 16:1	Oleic 18:1	Linoleic 18:2
Tallow	29.0	24.5	-	44.5	-
Coconut oil	5.0	3.0	-	6.0	-
Olive oil	14.6	-	-	75.4	10.0
Groundnut oil	8.5	6.0	-	51.6	26.0
Cotton oil	28.6	0.9	0.1	13.0	57.2
Corn oil	6.0	2.0	-	44.0	48.0
Soybean oil	11.0	2.0	-	20.0	64.0
Hazelnut kernel	4.9	2.6	0.2	81.4	10.5
Poppy seed	12.6	4.0	0.1	22.3	60.2
Rapeseed	3.5	0.9	0.1	54.1	22.3
Safflower seed	7.3	1.9	0.1	13.5	77.0
Sunflower seed	6.4	2.9	0.1	17.7	72.8
Castor oil	-	3.0	3.0	3.0	1.2

Edible vegetable oil is generally not used as fuel, but lower-quality oil can be used for this purpose. Used vegetable oil is increasingly being processed into biodiesel, or (more rarely) cleaned of water and particulates and used as a fuel. To ensure that the fuel injectors atomize the fuel in the correct pattern for efficient combustion, vegetable oil fuel must be heated to reduce its viscosity to that of diesel, either by electric coils or heat exchangers. This is easier in warm or temperate climates.

Vegetable oil can also be used in many older diesel engines that do not use common rail or unit injection electronic diesel injection systems. Due to the design of the combustion chambers in indirect injection engines, these are the best engines for use with vegetable oil. This system allows the relatively larger oil molecules more time to burn.

Oils and fats can be hydrogenated to give a diesel substitute. The resulting product is a straight chain hydrocarbon, high in cetane, low in aromatics and sulfur, and does not contain oxygen. Hydrogenated oils, which can be blended with diesel in all proportions, have several advantages over biodiesel, including good performance at low temperatures, no storage stability problems, and no susceptibility to microbial attack.

Volatile Matter

The amount of volatile products (volatile matter content) has a major impact on the tar production levels in gasifiers. Depending on the gasifier design, the volatile matter leaves the reactor at low temperatures (updraft gasifiers) or pass through a hot incandescent oxidation zone (downdraft gasifiers) where they are thermally cracked. For biomass materials, the volatile matter content varies between 50 and 80%.

Volatile matter is gases and vapors such as hydrogen, carbon monoxide, methane, tar, other hydrocarbons, carbon dioxide, and water obtained on pyrolysis. Volatile matter is the percentage of volatile products, exclusive of moisture vapor, released during the heating of coal or coke under rigidly controlled conditions. The measured weight loss of the sample corrected for moisture establishes the amount of material (volatile matter) evolved from the coal under the conditions of the test. However, the method, being empirical, requires close adherence to detailed specifications, and since the test is essentially an assay of the sample of coal on a small scale rather than a purely chemical test, it is necessary, in order that results may be comparable between different laboratories that the conditions prescribed must be followed rigidly.

The type of heating equipment and the size and shape of the sample holders as well as the material from which they are made (platinum crucibles specified) all have some influence on the rate of heating of the sample and the range of temperatures to which it is exposed. The crucibles used are 10 to 20 ml capacity of specified size with deep-fitting lids. And there are two procedures for determination of volatile matter.

The determination of the volatile matter content of a carbonaceous feedstock is an important because volatile matter data are an integral part of evaluating some feedstocks for suitability for combustion and carbonization. The methods for determining volatile matter content are based on the same principle and consist of heating a weighed sample of the feedstock (usually approximately 1 g) in a covered crucible to a predetermined temperature; the loss in weight (excluding losses due to water) is the volatile matter content (expressed as a weight percent).

Content

The term *volatile matter content* (of coal) is actually a misnomer insofar as the majority of the volatile matter is the volatile product of the thermal decomposition of coal through the application of high temperatures. The extent to which the more volatile smaller molecules of coal add to this is dependent on the coal and should be determined by other non-destructive methods such as extraction by solvent(s). Relative yields and boiling point profiles provide the extent to which natural molecules contribute to the volatile matter without any influence from high temperature cracking.

The volatile matter obtained during the pyrolysis of coal consists mainly of combustible gases such as hydrogen, carbon monoxide, methane plus other hydrocarbons; tar as well as incombustible gases such as carbon dioxide and steam are also evolved.

The moisture that can be evolved by heating to temperatures only slightly higher than the boiling point of water is not included here, but the water formed as part of the thermal decomposition process (and that originally existed as part of the coal substance but in a form other than water) is included.

The amount of volatile matter has a major impact on the tar production levels in gasifiers. Depending on the gasifier design, the volatile matter leaves the reactor at low temperatures (updraft gasifiers) or passes through a hot incandescent oxidation zone (downdraft gasifiers) where it is thermally cracked. For biomass materials, the volatile matter content varies between 50 and 80%.

Effect of Mineral Matter

Mineral matter may also contribute to the volatile matter by virtue of the loss of water from the clays, the loss of carbon dioxide from carbonate minerals, the loss of sulfur from pyrite (FeS_2), and the generation of hydrogen chloride from chloride minerals as well as various reactions that occur within the minerals, thereby influencing the analytical data.

The characterization of coal either as agglomerating or as non-agglomerating for the purposes of rank classification is carried out in conjunction with the determination of the volatile matter content. Thus, if the residue remaining from the determination is in the form of an agglomerate button that is capable of supporting a 500-g weight without pulverization of the button or if the button shows swelling or cell structure, the coal is classified as agglomerating.

Volatile Organic Compounds

Organic compounds that evaporate easily are collectively referred to as volatile organic compounds (VOCs). Microbial volatile organic compounds (MVOCs) are a variety of compounds formed in the metabolism of fungi and bacteria (Korpi et al., 2009). Typically, a volatile organic compound is any organic compound that will evaporate at the temperature of use and which, by a photochemical reaction, will cause oxygen in the air to be converted into smog-promoting ozone under favorable climatic conditions.

Thus, volatile organic compounds are gases that are emitted into the air from products or processes (Table 6.8). Some are harmful by themselves, including some that cause cancer. In addition, they can react with other gases and form other air pollutants after they are in the air. Many volatile organic compounds have been classified as toxic and carcinogenic. They are found in a wide variety of commercial, industrial, and residential products including fuel oils, gasoline, solvents, cleaners and degreasers, paints, inks, dyes, refrigerants, and pesticides. When volatile organic compounds are spilled or improperly disposed, they can soak into the soil and eventually end up in groundwater. Volatile organic compounds (VOCs) are found in almost all natural and synthetic materials and are commonly used in fuels, fuel additives, solvents, perfumes, flavor additives, and deodorants. Potential health hazards and environmental degradation resulting from the widespread use of volatile organic compounds has prompted increasing concern among scientists, industry, and the general public (Table 6.9).

Typically, volatile organic compounds are organic chemicals that have a high vapor pressure at ordinary room temperature. The high vapor pressure results from a low boiling point, which causes large numbers of molecules to evaporate from the liquid form or sublime from the solid form of the compound and enter the surrounding air. Volatile organic compounds are numerous, varied, and ubiquitous. They include both human-made and naturally occurring chemical compounds. Many volatile organic compounds are dangerous to human health or cause harm to the environment. Anthropogenic volatile organic compounds are regulated by law, especially indoors, where concentrations are the highest. Harmful volatile organic compounds typically are not acutely toxic, but have compounding long-term health effects.

Non-methane volatile organic compounds (NMVOCs) are a collection of organic compounds that differ widely in their chemical composition but display similar behavior in the atmosphere. NMVOCs are emitted into the atmosphere from a large number of sources including combustion activities, solvent use, and production processes. NMVOCs contribute to the formation of ground-level (tropospheric) ozone. In addition, certain NMVOC species or species groups such as benzene and 1,3 butadiene are hazardous to human health. Quantifying the emissions of total NMVOCs provides an indicator of the emission trends of the most hazardous NMVOCs.

Wood smoke forms when the wood is made up of a complex mixture of gases and fine particles (particulate matter, PM). In addition to particle pollution, wood smoke contains several toxic harmful air pollutants including benzene, formaldehyde, acrolein, and polycyclic aromatic hydrocarbon derivatives (PAHs, also known as polynuclear aromatic hydrocarbon derivatives, PNAs).

Wood smoke is by far the most compelling argument against wood heating. In cold climates, a frigid, stagnant air mass traps the smoke close to the ground. In the process of wood combustion, wood vaporizes when heated into gases and tar particles. If the temperature is high enough, the tar particles vaporize into chemicals and carbon particles. If the temperature is higher still and there is oxygen present, the gases and particles burn in bright flames.

Chemically, wood is approximately 50% w/w carbon, and the rest is mostly made up of oxygen and hydrogen. When a piece of wood is heated, it starts to smoke and turn black at the same time. This is because the other products vaporize under intense heat faster than the carbon burns, so smoking leaves much of the carbon behind until only charcoal remains. The smoke that vaporizes out of the wood is a cloud of nasty, gooey little droplets of a tar-like liquid. Chemically, these droplets are actually big, gooey, complicated hydrocarbon molecules that take a number of different forms, mostly bad.

When wood is burned correctly in a bright, hot, turbulent fire, what is observed is the tar droplets rising off the wood into a zone of extreme heat where they re-vaporize, undergoing thermal decomposition into (for the most part) gaseous constituents. This leaves carbon dioxide, some carbon monoxide and a number of other gases, water vapor, and some not quite completely oxidized hydrocarbon products (typically identified as particulate emissions).

The sentiment that wood smoke, being a natural substance, must be benign to humans is still sometimes heard. It is now well established, however, that wood-burning stoves and fireplaces as well as wild fires and agricultural fires emit significant quantities of known health-damaging pollutants, including several carcinogenic compounds (Naeher et al., 2007). Two of the principal gaseous pollutants in wood smoke, carbon monoxide (CO) and the oxides of nitrogen (NO_x), add to the atmospheric levels of these regulated gases emitted by other combustion sources. Thus, there are two issues related to wood smoke and they are (i) whether or not woodsmoke should be regulated and/or managed separately, even though some of the individual constituents are already regulated in many jurisdictions and (ii) whether or not woodsmoke particles pose different levels of risk than other ambient particles of similar size.

The particulate matter wood smoke is extremely small and therefore are not filtered out by the nose or the upper respiratory system. Instead, these small particles end up deep in the lungs where they remain for months, causing structural damage and chemical changes. The carcinogenic chemicals in wood smoke adhere to these tiny particles, which enter deep into the lungs.

Volatile organic compounds (VOCs) are regulated because they are precursors to ozone: carbon-containing gases and vapors from incomplete gasoline combustion and from the evaporation of solvents.

A wide range of carbon-based molecules, such as aldehyde derivatives, ketone derivatives, and other low-boiling hydrocarbon derivatives fall within the class of volatile organic compounds. The term is often used in a legal or regulatory context, and in such cases, the precise definition is a matter of law. These definitions can be contradictory and may contain loopholes such as exceptions, exemptions, and exclusions. The United States Environmental Protection Agency (EPA) defines volatile organic compounds as any organic compound that participates in a photoreaction;

others believe this definition is broad and vague as organics that are not volatile in the sense that they vaporize under normal conditions can be considered volatile by this definition. The term may refer both to well-characterized organic compounds and to mixtures of variable composition.

See also: Wood Smoke.

Volatility, Flammability, and Explosive Properties

The boiling point (boiling temperature) of a substance is the temperature at which the vapor pressure of the substance is equal to atmospheric pressure. At the boiling point, a substance changes its state from liquid to gas. A stricter definition of boiling point is the temperature at which the liquid and vapor (gas) phases of a substance can exist in equilibrium. When heat is applied to a liquid, the temperature of the liquid rises until the *vapor pressure* of the liquid equals the pressure of the surrounding atmosphere (gases). At this point, there is no further rise in temperature, and the additional heat energy supplied is absorbed as *latent heat* of vaporization to transform the liquid into gas. This transformation occurs not only at the surface of the liquid (as in the case of *evaporation*) but also throughout the volume of the liquid, where bubbles of gas are formed. The boiling point of a liquid is lowered if the pressure of the surrounding atmosphere (gases) is decreased. On the other hand, if the pressure of the surrounding atmosphere (gases) is increased, the boiling point is raised. For this reason, it is customary when the boiling point of a substance is given to include the pressure at which it is observed, if that pressure is other than standard, i.e., 760 mm of mercury or 1 atmosphere (STP, Standard Temperature and Pressure).

The boiling points of fuels from conventional sources and from renewable energy sources are rarely, if ever, distinct temperatures and it is, in fact, more correct to refer to the boiling ranges of the various fractions. To determine these ranges, the material in question is tested in various methods of distillation, either at atmospheric pressure or at reduced pressure. Thus, the boiling points of the hydrocarbon constituents increase with molecular weight, and the initial boiling point of a (gaseous or liquid) mixture corresponds to the boiling point of the most volatile constituent.

The *flash point* of a fuel is the temperature to which the product must be heated under specified conditions to give off sufficient vapor to form a mixture with air that can be ignited momentarily by a specified flame. As with other properties, the flash point is dependent on the composition of the fuel.

The *fire point* is the temperature to which the fuel must be heated under the prescribed conditions of the method to burn continuously when the mixture of vapor and air is ignited by a specified flame. In addition to the fire point, and also from the viewpoint of safety, information related to the flash point is of most significance at or slightly above the maximum temperatures that may be encountered in storage, transportation, and use of the fuel in either closed or open containers. In this temperature range, the relative fire and explosion hazard can be estimated from the flash point. For products with flash point below 40°C (104°F), special precautions are necessary for safe handling. Flash points above 60°C (140°F) gradually lose their safety significance until they become indirect measures of some other quality.

A further aspect of volatility that receives considerable attention is the vapor pressure of the fuel. The *vapor pressure* is the force exerted on the walls of a closed container by the vaporized portion of a liquid. Conversely, it is the force that must be exerted on the liquid to prevent it from vaporizing further. The temperature at which the vapor pressure of a liquid fuel (which may be a pure compound or a mixture of many compounds) equals 1 atmosphere (14.7 psi, absolute) and is designated as the boiling point of the liquid.

The flammable range is expressed by the lower explosive limit (LEL) and the upper explosive limit (UEL). The lower explosive limit is the concentration of the fuel in the air below which the propagation of a flame will not occur on contact with an ignition source. The upper explosive limit is the concentration of the fuel in the air above which the propagation of a flame will not occur on contact with an ignition source.

Walker Circulation

In a manner similar to the Hadley Cell that transports air from the equator to the sub-tropical latitudes (meridional circulation), there are zonal mean circulations (east-west oriented). One of these, the Walker circulation, plays a primary role in determining where rainfall will fall near equatorial regions and throughout the globe. Under normal conditions, the easterly trade winds move warm surface waters westward, causing higher temperatures in the western Pacific. The air overlying this warm water is in turn heated and rises to high levels of the atmosphere, diverges outwards, east and west, and finally sinks over the eastern Pacific. Rising air is associated with a region of low pressure, towering cumulonimbus clouds, and rain. High pressure and dry conditions accompany the sinking air. There is also upwelling of cold nutrient-rich water off the coast of Peru.

However, in contrast to the Hadley, Ferrel, and polar circulations that run along north-south lines, the Walker circulation is an east-west circulation. Over the eastern Pacific Ocean, surface high pressure off the west coast of South America enhances the strength of the easterly trade winds found near the equator. The winds blow away from the high pressure toward lower pressure near Indonesia. Upwelling, the rising of colder water from the deep ocean to the surface, occurs in the eastern Pacific along South America near Ecuador and Peru.

This cold water is especially nutrient-rich and is stocked with an abundance of large fish populations. By contrast, the water in the western Pacific, near Indonesia, is relatively warm. The air over Indonesia rises because of the surface low pressure located there and forms clouds. This causes heavy precipitation to fall over the western tropical Pacific throughout the year. The air then circulates back aloft toward the region above the surface high pressure near Ecuador, and this becomes the Walker circulation. The air sinks at this surface high pressure and is picked up by the strong trade winds to continue the cycle.

On some occasions, the Walker circulation and the trade winds weaken, allowing warmer water to move toward the eastern tropical Pacific near South America. This warming of the eastern Pacific Ocean (El Niño) allows the warmer water to also serve as a source for warm, moist air which can aid in the development of heavy thunderstorms over the mass of warm water.

Waste

Waste is the remains or by-product from a process for which no use is planned or foreseen. The words domestic (or municipal) and industrial are qualifiers of the source of the waste and, to some extent, also descriptive of the contents of the waste. Once a material has been designated as waste, it remains waste until it has been fully recovered and no longer poses a potential threat to the environment.

Thus, domestic waste (also known as rubbish, garbage, trash, or junk) is unwanted or undesired material (although the old adage one man's waste is another man's treasure sometimes applies). Waste is the general term; though the other terms are used loosely as synonyms, they have more specific meanings: rubbish or trash are mixed household waste including paper and packaging; food waste or garbage (North America) is kitchen and table waste, and junk or scrap is metallic or industrial material. There are other categories of waste as well: sewage, ash, manure, and plant materials from garden operations, including grass cuttings, fallen leaves, and pruned branches.

On the other hand, industrial waste is waste type produced by industrial factories, mills, and mines. It has existed since the outset of the industrial revolution. Toxic waste and chemical waste are two more specific designations of industrial waste.

Municipal solid waste (MSW) is a waste type (Table W-1) that originates from various sources (Table W-2) and includes predominantly household waste (domestic waste) with sometimes the addition of commercial wastes

collected by a municipality within a given area. They are in either solid or semisolid form and generally exclude industrial hazardous waste. The term residual waste relates to waste left from household sources containing materials that have not been separated out or sent for reprocessing.

Table W-1 Types of waste.

Type	Description
Food waste	Animal, fruit, or vegetable residues (also called garbage) that result from the handling, preparation, cooking, and eating of foods. Also, food wastes are subject to putrefaction insofar as they will decompose rapidly, especially in warm weather.
Garbage (rubbish)	Combustible and non-combustible solid wastes, excluding food wastes or materials subject to putrefaction. Typically combustible rubbish consists of materials such as paper, cardboard, plastics, textiles, rubber, leather, wood, furniture, and garden (landscaping) trimmings. Non-combustible garbage rubbish consists of items such as glass, crockery, tin cans, aluminum cans, ferrous and non-ferrous metals, dirt, and construction material.
Ash	Materials ranging from the burning of wood, coal, coke, and other residues of combustible wastes. Ash and residues are typically composed of fine powder, cinders, clinkers, and small amounts of burned and partially burned materials.
Demolition/construction	Wastes from razed buildings and other structures are classified as construction demolition wastes as are wastes from the construction, remodeling, and repairing of residential, commercial, and industrial buildings and similar structures are classified. These wastes may include dirt stones, concrete, bricks, plaster, lumber, shingles (tiles) as well as plumbing, heating waste, and electrical parts. These waste are usually of an inert nature. The main exception is asbestos for which special disposal is required.
Treatment plant waste	The solid and semi-solid wastes from water, sewage, and industrial wastewater treatment facilities are included in this classification. Sewage sludge is a slurry of fine organic-rich particles with a highly variable chemical composition depending on the source of the effluent as well as the types and efficiency of the treatment process. Sewage sludge tends to concentrate heavy metals and water-soluble synthetic organic compounds but may also contain grease, oil, and bacteria. Dredged materials are those materials that are excavated from river estuaries, harbors, and other waterways to aid navigation. Much of the dredged material may be contaminated crude oil, crude oil products, heavy metals, nutrients, and organo-chlorine compounds.
Other (special) waste	Wastes such as street sweepings, roadside litter, catch-basin debris, dead animals, abandoned vehicles, and electrical appliances fall into the class of special waste.

Table W-2 Sources of municipal waste.

Source	Types
Residential	Food waste Garbage Ash Hazardous waste
Commercial	Food waste Garbage Ash Demolition waste Construction waste Treatment plane sludge Hazardous waste

There are five broad categories of municipal solid waste which are (i) biodegradable waste such as food and kitchen waste, green waste, and paper – which can also be recycled, (ii) recyclable material such as paper, glass, bottles, cans, metals, and certain plastics, (iii) inert waste such as construction and demolition waste, dirt, rocks, and debris, (iv) composite waste which includes waste clothing and waste plastics such as toys, and (v) domestic hazardous waste (also called household hazardous waste) and toxic waste such as discarded medications, paint, chemicals, light bulbs, fluorescent tubes, spray cans, fertilizer containers, pesticide containers, batteries, and shoe polish.

There is also electronic waste which is a waste consisting of any broken or unwanted electrical or electronic appliance. While there is no generally accepted definition of electronic waste, in most cases, electronic waste consists of electronic products that were used for data processing, telecommunications, or entertainment in private households and businesses that are now considered obsolete, broken, irreparable, or of no further use due to planned obsolescence. Despite its common classification as a waste, disposed electronics are a considerable category of secondary resource due to their significant suitability for direct reuse (for example, many fully functional computers and components are discarded during upgrades), refurbishing, and material recycling of its constituents.

It is a point of concern considering that many components of such equipment are considered toxic and are not biodegradable but they are not precursors to fuels and, other than recognition though the above paragraph, will not be considered in the context of the present text.

In nature, there is no waste; on the other hand, waste is a by-product of the human economic system and the technology that drives it. Since the industrial revolution, human society has developed economies that are largely unrelated from nature and the natural order of events. They have created public and private wealth, material well-being, a plentiful food supply, comfortable living conditions, personal freedoms, and enhanced culture, but at a price.

In modern society, waste comes in a variety of forms and must be dealt with on a day-to-day basis. Industry produces huge amounts of industrial waste, and domestic waste makes a large contribution to the general waste problem. In spite of the recognition, many insidious waste products escape (inadvertently or deliberately) into the surrounding environment. Thus, there are numerous pollution incidents. On the other hand, there are technologies available for the treatment of most of the wastes produced. The level of treatment is largely a matter of cost, but conversion of waste to new products is a concept that has long been ready to hatch. Now is the time.

Waste Biomass

Biomass is the material derived from plants that use sunlight to grow which includes plant and animal material such as wood from forests, material left over from agricultural and forestry processes, and organic industrial, human, and animal wastes. More simply, biomass is stored energy. During photosynthesis, plants use light from the Sun's energy (light energy) to convert carbon dioxide and water into simple sugars and oxygen.

In nature, if biomass is left undisturbed on the ground, it will break down over a long period of time, releasing carbon dioxide and its store of energy slowly. By burning biomass, its store of energy is released quickly and often in a useful way. So converting biomass into useful energy imitates the natural processes but at a faster rate.

Biomass wastes can be transformed into clean energy and/or fuels by a variety of technologies, ranging from conventional combustion process to state-of-the-art thermal depolymerization technology. Besides recovery of substantial energy, these technologies can lead to a substantial reduction in the overall waste quantities requiring final disposal, which can be better managed for safe disposal in a controlled manner while meeting the pollution control standards.

Biomass wastes can be transformed into clean energy and/or fuels by a variety of technologies, ranging from conventional combustion process to state-of-the-art thermal depolymerization technology. Besides recovery of substantial energy, these technologies can lead to a substantial reduction in the overall waste quantities requiring final disposal, which can be better managed for safe disposal in a controlled manner while meeting the pollution control standards.

Waste – Domestic and Industrial

Industrial waste is waste type produced by industrial factories, mills, and mines. It has existed since the outset of the industrial revolution. Toxic waste and chemical waste are two designations of industrial waste.

Domestic waste is waste from householders which cannot be recycled, composted, reused, or disposed of by other means.

Much of what human society discards contains usable material, much of it in the form of recoverable energy. Paper, wood, cloth, food waste, and plastics are the main potential energy sources in waste. The remainder of the waste consists of glass, metals, and miscellaneous rubble. Domestic waste is typically disposed of by tipping it into large holes in the ground – landfill sites. Sometimes, the waste is incinerated first, and only the remaining ash and non-combustible material is sent to a landfill. Increasingly, a proportion of the waste is being separated for recycling at some stage along the way.

It is possible to recover energy from landfill sites and from waste incinerators. Domestic waste could also provide feedstock for a number of other conversion systems, all of which could recover useful energy while reducing the requirement for landfill sites. However, whatever the energy technology, domestic waste is a low-grade fuel. Its consistency is variable and not well suited to mechanical handling systems; the proportions of the various constituents will vary from load to load; the moisture content and heating value will vary; and the proportion of non-combustible material will keep the heating value low. All of this can lead to inefficient combustion if the process is not well controlled, making it more difficult to control toxic emissions from plastics and other materials.

There is also a potential conflict between the recycling of materials and the recovery of energy from those materials. The main benefit of domestic waste as a fuel source is that, as with most other waste streams, energy technology can reduce the waste disposal problem.

Recently, interest has grown in the burning of garbage/domestic waste to produce electricity. This is not a new idea, although in the past, when waste was burned, it created pollution that could even be toxic. Today, the technology exists to remove almost all the pollutants from the fumes produced during the energy production cycle. Special filters remove dangerous chemicals and particles that would normally be found in the fumes. The domestic waste is sorted usually by hand to remove materials than can be recycled. Steel is removed using electromagnets, and this is stored until there is enough quantity for recycling to be economically viable. Aluminum, in the form of cans is removed by hand. The waste is then fed into the hopper of a furnace. When the doors slide open, it falls into the burning chamber. Gas is normally used to start the fire which burns at a high temperature, destroying the domestic waste. While the waste burns, it heats a water tank, in turn, producing steam. The steam is used to turn turbines, producing electricity. Once steam has been produced, the production of electrical power is no different than that used in any other power station. The high-pressure steam is used to turn electrical turbines which produce electricity. The advantage of this way of producing electricity is that the domestic waste that would normally be buried in landfill sites or even dumped far out at sea is burned. This means that vast areas of land that would have to be used for landfill are free for agriculture or for building.

See also: Municipal Solid Waste, Urban Waste.

Waste – Effects of

Wastes generated from the domestic and industrial sources increase continuously with rising population. In general, the lack of facilities for disposal of waste caused overall of landfill sites resulting in hazards for the environment and for public health. These effects include the following: (i) air pollution, (ii) pollution of surface waters, (iii) changes in soil fertility, and (iv) changes in the landscape and visual discomfort.

Air pollution by unpleasant odors and wind-carried suspensions is obvious in areas located nearby urban waste landfills, since these are currently run in complete ignorance of practices such as cell operation and inert matter lagging. The leakage on the slopes of landfills situated nearby surface water bodies adds to the pollution of such waters by organic substances and suspensions. The urban waste landfills that are not waterproof often represent sources of

groundwater pollution by nitrates and nitrites, as well as other pollutants. Water leakage adversely affects the quality of the adjoining soils, which brings along consequential effects to their utilization.

Withdrawing land from the natural or economic circuit in order to set up waste landfills is a process which may be regarded as temporary, yet, in terms of sustainable development, it extends over at least two generations when adding up the time periods required for planning works (1 to 3 years), running (15 to 30 years), ecological reconstruction, and subsequent monitoring (15 to 20 years).

In terms of biodiversity, any domestic or industrial waste landfill means the subsequent elimination of a number of 30 to 300 species (microbiological population of the soil not included) on each hectare of the area intended to host a landfill. Moreover, changes are likely to occur in areas close to the landfill, such as (i) ruderal species, i.e., plant species that are first to colonize disturbed lands that are specific to polluted areas would become dominant in the vegetal assemblies, and (ii) some mammals, birds, and insects would desert the area, in favor of species that feed on refuse (rats, crows).

Although the effects on flora and fauna are, in theory, time limited to the period over which the landfill is operated, the ecological reconstruction performed after the area has been relieved from its technological use will not be able to retrieve the initial biological balance, as the evolution of that biosystem has been irreversibly modified. The practices used currently in the collection, transport, and storage of urban waste facilitate the multiplication and dissemination of the pathogenic agents and their accompanying breed: insects, rats, crows, and stray dogs.

Thus, waste in any form (domestic or industrial) represents a health hazard, due to its dispersal and composition. In terms of composition, the focus is often on toxic substances such as heavy metals (lead, cadmium), pesticides, solvents, and used oils that form an integral part of the waste.

Indeed, the challenge for waste disposal arises from the joint storage of hazardous materials (including toxic sludge, oil products, dyeing residues, and metallurgical slag) and solid domestic waste. This situation is likely to generate inflammable, explosive, or corrosive mixtures and combinations thereof. On the other hand, the presence of easily degradable household may facilitate the decomposition of complex hazardous components, and thus diminish environmental pollution.

Another negative aspect is the fact that several recyclable and useful materials are stored in the same place as materials that cannot be recycled; consequently, these materials blend together and become chemically and biologically contaminated, which renders their retrieval rather difficult.

Thus, the problems faced by waste management activities may be summarized as follows: (i) storage in open grounds is the most used method to remove waste ultimately, (ii) existing landfills may be located in sensitive places (i.e., in the close proximity to lodgings, surface or ground water, leisure areas), (iii) existing waste landfills may be improperly designed from an environmental protection point of view, thus allowing for water and soil pollution in those areas, and (iv) currently, waste landfills may require a review of waste handling practices insofar as waste layers are not compacted and there is no strict control of the quality and quantity of waste that is dumped on the landfill leading to the potential for fire and/or the emanation of unpleasant odors.

All of the above lead to the conclusion that specific measures need to be taken with regard to waste management, which would be adequate in each phase of the waste dumping process. Environmental monitoring activities should comprise the observance of these measures. However, one answer to these issues is to convert the waste to usable products either through (i) the production of gaseous fuels, or (ii) the production of liquid fuels, or (iii) the production of solid fuels.

Such efforts may not only solve the depletion of fuels from fossil sources but also assist in the disposal of waste materials and the ensuing environmental issues. However, before entering upon the process descriptions for waste conversion, it is necessary to understand the composition of domestic and industrial waste.

The term waste incorporates a number of streams in a modern society. Relevant to gasification, pyrolysis, and incineration are streams such as chemical waste, medical waste, waste from auto-shredder, paper, plastics, textiles, metals, glass, and sundry other components which may form part of the industrial waste and domestic waste. Like feedstocks for any process, these raw materials require different processes for optimal operation.

Generating waste at current levels is incompatible with a sustainable future. While the problem of waste is serious, a variety of initiatives are being taken to address the various threats. These include moves toward waste minimization, waste segregation, and recycling, cleaner production with regular waste audits, green chemistry, renewable

energy and energy efficiency, and developing the concept of industrial ecosystems. The issues involved are much more than technical problem.

The historic approach to solid waste has been to bury it in landfill. This is becoming increasingly problematic because the diminishing availability of suitable landfill sites and the increasingly stringent conditions being applied to landfill mean that charges have increased and will continue to increase. Major problems associated with landfills are the leachate containing toxic heavy metals and the methane gas that is produced.

This is a major issue because of the variability of industrial solid, liquid, and gaseous wastes, and the capacity of modern processing industries to produce huge quantities of waste. Fortunately, regulatory processes are now such that the numerous disasters caused previously should not be repeated. However there are remaining problem sites that constitute long-term hazards.

Thus, in order to reduce the amount of landfill, the amount of waste must be reduced. This involves either (i) cutting back on the use of many materials or (ii) use of the waste by conversion to useful products. Either option would reduce the amount of waste sent to landfill sites. The first option certainly reduces the amount of landfill material but is often more difficult to achieve. However, the second option offers the attractive proposition of the production of fuel products. Thus, waste conversion becomes an attractive option to landfill disposal, and the result is the generation of a usable product in the form of a gaseous, liquid, or solid fuel.

However, ancillary of the second option is the heterogeneity of waste material. In fact, it is obvious that many waste streams are not subject to direct processing and will require special measures in the form of specific pretreatment of the waste prior to processing.

One form of pretreatment is separation and recycling of waste components, thereby removing a portion of the waste stream for recycling and other uses. The result of this separation at the source is the remaining residual waste (i.e., the waste stream from which recyclable materials have been removed) that is not destined for any use other than landfill is sent to the conversion reactor.

Waste – Fuels From

A significant number and variety of organic wastes are combusted in energy recovery systems including municipal solid waste, various forms of refuse-derived fuel produced from municipal solid waste as well as a broad range of other specific specialty wastes. The practice of incinerating waste has become increasingly prevalent in order to accomplish disposal in an environmentally sensitive manner. Combustion of such wastes reduces the volume of material which must be sent to a landfill, reduces the airborne emissions resulting from plant operations and landfill operations, and permits some economic benefit through energy recovery.

The technologies used to combust wastes depend on the form and location of components to be burned. The issues associated with energy generation from waste include fuel composition characteristics, combustion characteristics, formation and control of airborne emissions including both criteria pollutants and air contaminants (such as trace metals), and the characteristics of bottom and fly ash that is generated from waste combustion.

The concept of the incineration of domestic and industrial waste to gaseous fuels is one of the first suggestions from the disposal of waste and the generation of energy. With this in mind, waste incineration has been, and continues to be, practiced in many parts of the world. In fact, co-combustion of waste in (large and efficient) coal-fired power plants is an especially attractive option because of the high conversion efficiency of these plants. However, there are issues that need attention, and while it is not intended here to use the following comments to be a critique of waste incineration, here are lessons to be learned and changes to be made in this manner of waste removal.

Although not in keeping with the main context of this text, i.e., the production of fuels, the incineration of wastes is worthy of mention insofar as waste combustion (although the main goal of incineration is volume reduction with the sterilization of the waste as a significant side-effect) can be a source of energy but, generally. Thus, the incineration process may also be used to produce steam and electricity. However, as the moisture content of the waste increases, a self-sustaining combustion process is not possible. Nevertheless, domestic waste and industrial waste are feedstocks for incinerators.

Nevertheless, incineration is recognized as a waste treatment technology for disposal of the organic constituents of the waste. Incineration and other high-temperature waste treatment systems convert the waste into ash, flue gases, particulate matter, and heat, which can in turn be used to generate electricity. The flue gases are cleaned for pollutants before it is dispersed in the atmosphere. Furthermore, incineration with energy recovery is one of several waste-to-energy technologies which include gasification and anaerobic digestion.

Modern incinerators reduce the volume of the original waste by 95 to 96%, depending upon composition and degree of recovery of materials such as metals from the ash for recycling. While incineration does not replace land-filling, it does reduce the necessary volume significantly. In fact, incineration has particularly strong benefits for the treatment of certain types of waste in niche areas such as clinical waste and certain hazardous waste where pathogens and toxins can be destroyed by high temperatures.

The incinerator is, simply, a furnace for burning refuse, and modern incinerators include pollution mitigation equipment such as flue-gas cleaning. The incinerator must be designed to ensure that the flue gas reaches a temperature of at least 850°C (1,560°F) in order to ensure proper breakdown of organic toxins. This includes backup auxiliary burners (often fueled by oil), which are fired into the boiler in case the heating value of the waste becomes too low to reach this temperature alone. The flue gas is then cooled by heat transfer and heat the steam to typically 400°C (750°F) at a pressure of 550 to 600 psi for the electricity generation in the turbine. At this point, the flue gas has a temperature of around 200°C (390°F), and is passed to the flue gas cleaning system. There are various types of incinerator plant design: (i) simple incinerator, (ii) fixed or moving grate incinerator, (iii) rotary-kiln incinerator, and (iv) the fluidized bed incinerator.

The *simple incinerator* is an older and simpler kind of incinerator that is, essentially, a brick-lined cell with a metal grate over a lower ash pit, with one opening in the top or side for loading and another opening in the side for removing incombustible solids (clinker). Many small incinerators formerly found in apartment houses have now been replaced by waste compactors. The *fixed* or *moving grate incinerator* is a fixed hearth incinerator with a moving grate. The moving grate enables the movement of waste through the combustion chamber to be optimized to allow a more efficient and complete combustion. These incinerators are typically used for combustion of municipal waste, and are thus referred to as municipal solid waste incinerators (MSWIs).

In the *fixed* or *moving grate incinerator*, the waste is introduced by a waste crane through the “throat” at one end of the grate, from where it moves down over the descending grate to the ash pit in the other end. Here the ash is removed through a water lock. Part of the combustion air (primary combustion air) is supplied through the grate from below. This air flow also has the purpose of cooling the grate itself. Cooling is important for the mechanical strength of the grate, and many moving grates are also water cooled internally. Secondary combustion air is supplied into the boiler at high speed through nozzles over the grate. It facilitates complete combustion of the flue gases by introducing turbulence for better mixing and by ensuring a surplus of oxygen.

The rotary kiln incinerator has a primary chamber and secondary chamber. The primary chamber consists of an inclined refractory lined cylindrical tube. Movement of the cylinder on its axis facilitates movement of waste. In the primary chamber, there is conversion of solid fraction to gases, through volatilization, destructive distillation, and partial combustion reactions. The secondary chamber is necessary to complete gas phase combustion reactions. The clinker spills out at the end of the cylinder. A tall flue gas stack, fan, or steam jet supplies the needed draft. Ash drops through the grate, but many particles are carried along with the hot gases. The particles and any combustible gases may be combusted in an *afterburner*. To control air pollution, the combustion product gases are further treated with acid gas scrubbers to mitigate sulfuric acid and nitric acid emissions, and then routed through bag houses to remove particulate matter before the gases are released into the atmosphere.

The *fluidized bed incinerator* uses a strong airflow through a sand bed until a point is reached where the sand particles separate to let the air through and mixing and churning occurs, thus a fluidized bed is created and fuel and waste can now be introduced. The sand with the pre-treated waste and/or fuel is kept suspended on pumped air currents and takes on a fluid-like character. The bed is thereby thoroughly mixed and agitated keeping small inert particles and air in a fluid-like state. This allows all of the mass of waste, fuel, and sand to be fully circulated through the furnace.

The heat produced by an incinerator can be used to generate steam which may then be used to drive a turbine in order to produce electricity. However, the amount of energy produced is very much dependent upon the type and composition of the waste used as the feedstock. Much of the current thinking involves co-incineration of a specified

amount of the waste (calculated on the basis of the carbon content of the waste) with, for example, coal to produce a consistent amount of energy.

Incineration has a number of outputs such as the ash and the emission to the atmosphere of flue gas. Before the flue gas cleaning, the flue gases may contain significant amounts of particulate matter, heavy metals, dioxin derivatives, furan derivatives, sulfur dioxide, hydrochloric acid, and polynuclear aromatic hydrocarbon derivatives (carcinogens). The most publicized concerns related to the incineration of municipal solid wastes involve the fear that it produces significant emissions of furan derivatives and dioxin derivatives, which are considered to be serious health hazards.

Older generation incinerators that were not equipped with modern gas cleaning technologies were indeed significant sources of dioxin emissions. However, modern incinerators (due to advances in emission control designs and stringent regulations) must limit and even mitigate such emissions.

Particulate matter is collected by particle filtration, most often electrostatic precipitators and/or baghouse filters. Hydrogen chloride and sulfur dioxide are removed in scrubbers or by dry desulfurization in which a limestone slurry ($\text{CaCO}_3/\text{H}_2\text{O}$) is injected into the flue gas before the particle filtration. Wastewater from scrubbers must subsequently pass through a wastewater treatment plant. Nitrogen oxide (NO_x) emissions are either reduced by catalytic reduction with ammonia in a catalytic converter (selective catalytic reduction) or by a high temperature reaction with ammonia in the furnace (selective non-catalytic reduction). Heavy metals are often adsorbed on injected activated carbon powder, which is collected by the particle filtration.

Incineration produces fly ash and bottom ash just as is the case when coal is combusted. The total amount of ash produced by municipal solid waste incineration ranges from 15 to 20% w/w of the waste, and the fly ash amounts to 0 to 10% w/w of the total ash. The fly ash, by far, constitutes more of a potential health hazard than does the bottom ash because the fly ash often contains high concentrations of heavy metals such as lead, cadmium, copper, and zinc as well as small amounts of dioxin derivatives and furan derivatives. The bottom ash seldom contains significant levels of heavy metals.

While fly ash is always regarded as hazardous waste, bottom ash is generally considered safe for regular landfill after a certain level of testing defined by the local legislation. Ash, which is considered hazardous, may generally only be disposed of in landfills which are carefully designed to prevent pollutants in the ash from leaching into underground aquifers – or after chemical treatment to reduce its leaching characteristics.

In spite of the promise shown by the use of incinerators for waste disposal and, in some cases, energy production (in the form of fuel gases), the use of incinerators for waste management is controversial. On the one hand, concerns over the health effects of dioxin and furan emissions have been significantly lessened by advances in emission control designs and very stringent new governmental regulations that have resulted in large reductions in the amount of dioxins and furans emissions. Also, modern incineration plants generate electricity and heat that can be sold to the regional electric grid and can sell steam to district heating systems or industrial customers. The bottom ash residue remaining after combustion has been shown to be a non-hazardous solid waste that can be safely landfilled or possibly reused. In densely populated areas, finding space for additional landfills is becoming increasingly difficult.

Incineration of municipal solid waste avoids the release of carbon dioxide and methane. Every ton of municipal solid waste incinerated prevents approximately one ton of carbon dioxide equivalents from being released to the atmosphere. Incineration of medical waste and sewage sludge produces an end product ash that is sterile and

non-hazardous. On the other hand, the end product ash must still be safely disposed. Many countries deny the use of incineration as an option for the treatment of their municipal solid wastes because of the potential of environmental pollution.

Incinerators emit varying levels of heavy metals such as vanadium, manganese, chromium, nickel, arsenic, mercury, lead, and cadmium which can be toxic at very minute levels. Other advanced alternative technologies are available such as biological treatment combined with anaerobic digestion and gasification. Incinerators produce soot particles ($PM_{2.5}$, nanoparticles or particles with a size less than 2.5 microns, i.e., $<1 \times 10^{-6}$ meter) in the furnace. Even with modern particle filtering of the flue gases (e.g., baghouse filters), some of these small particles are emitted to the atmosphere.

Although waste combustion can be used to generate power, a portion of that power is consumed by fans, pumps, and other electrically powered components. However, with the ban on landfilling untreated waste in various countries, modern design waste-to-energy plants have been built in the last decade, with more under construction, and there is renewed interest in waste-to-energy.

In summary, incineration is not a complete method of disposal; its main advantage is that it produces a residue that is substantially reduced in volume and may be relatively inert. In addition, the efficiency of an incinerator is, on occasion, due to excessive throughput or choice of operating parameters that are less than desired. For example, the operating temperature inside the plant should be at the specified temperature (usually approximately 850°C, 1,560°F) to reduce the possible effects of the most dangerous air pollutants and the production of dioxins. A lower than specified combustion temperature implies incomplete incineration, leaving part of the waste in the ashes and other combustion residues. Furthermore, the exhaust gases may be unnecessarily polluting because of the low combustion temperature, and the by-products of such combustion may be sent to an unprotected landfill for disposal.

Gaseous Fuels

There are two ways of producing gaseous fuel from waste: (i) gasification of the waste at high temperatures by partial oxidation and then conversion of materials containing carbon into synthesis gas (mainly hydrogen and carbon monoxide) and (ii) production of biogas, mainly methane, by the anaerobic digestion of waste.

Gasification is the general term used for processes where heat is used to transform a feedstock, usually a solid feedstock such as coal or biomass or wood into a gaseous fuel. Similarly, the gasification process is also applicable to the conversion of any solid carbonaceous waste to a clean-burning gaseous fuel. Whether starting with coffee grounds, municipal trash, or junk tires, the end product is a flexible gaseous fuel, and with the relevant process modifications, production of liquid and solid fuels is also possible. Biochemical conversion options can be divided into digestion (production of biogas, a mixture of mainly methane and carbon dioxide) and fermentation (production of ethanol). With respect to thermochemical conversion options, a distinction can be made between combustion, gasification, and pyrolysis.

Anaerobic digestion is a process whereby organic waste is broken down in a controlled, oxygen-free environment by bacteria naturally occurring in the waste material. Methane-rich biogas is produced, thus facilitating renewable energy generation. As a result, materials that are currently going to landfill can be utilized; natural methane emissions are reduced, and conventional generation with its associated carbon emissions is displaced. The residual nutrient-rich liquor and digestate are suitable for use as fertilizer on the farmland surrounding such a plant, reducing the need for artificial fertilizer. In summary, anaerobic digestion is a form of composting and its use for the conversion of waste to gaseous fuel by anaerobic processes.

The concept of the production of fuel gas by gasification of waste is not new – solid wastes were somewhat in focus for the gasification and pyrolysis activities; around 1970, biomass gasification took over the central role when the oil prices went up after 1973 which is reflected in the development of a wide range of processes. Most of the processes were designed for wood or wood waste, and, surprisingly, some of these processes have also been proposed for waste handling and are taking up the move to commercialization that was last evident two decades ago.

The chemical principle behind waste gasification and the production of gaseous fuels is that waste contains carbon and it is this carbon that is converted to gaseous products via the usual gasification chemistry. Thus, when fuel is fed to a gasifier, water and volatile matter are released fast and a char residue is left to react further. The char gasification is what mainly controls the conversion achieved in the process. From solid carbon, product gas is formed according to the following main reactions:

In addition to the reactions of solid carbon, the most important reaction is the water-gas shift reaction, which takes place in the gas phase:

The product gas generally contains large amounts of hydrogen and carbon monoxide and a small amount of methane, as well as carbon dioxide and steam, and in air gasification nitrogen. In addition, a significant amount of other organic components in the gas, known as tar, is formed. Tar formation is a well-known phenomenon in the thermal reactions of coal and can also be anticipated to form in the gasification or pyrolysis of any complex carbonaceous material.

Biomass-based fuels (and many components of domestic and industrial waste can be included in this category) are non-fossil fuels. Vegetative biomass can be classified into the categories woody, herbaceous, agricultural by-products, energy crops, and black liquor (a by-product of the forest industry). Because of the high concentration of organic materials in industrial waste and in domestic waste (including discarded food), many constituents of waste are actually biomass. But the issues arise from the other constituents of the waste that make the waste truly heterogeneous and, in many cases, of indeterminate composition.

Most of the reactors were of the fixed-bed type (updraft or downdraft) and are considered to be adequate processes for local use in terms of the alternate, i.e., landfilling the waste. However, whether wastes should be handled locally or in large scale, centralized units are another issue that is still under debate.

Thus, a process for waste gasification must be chosen to reflect the character of the waste relation to the main questions in this report as stated in the introduction. However, a few of the original processes touted as potential methods for waste gasification may not be in current commercial use and reference must be made to gasification processes (for coal) that are in current commercial use.

The reason for the overall lack of commercial processes for waste gasification hinges on several areas. For example, most of the processes proposed for waste gasification did not include a separation step. Feedstock homogeneity is a pre-requisite for many gasifiers, and feedstock heterogeneity and process scale-up can lead to a number of mechanical problems, shut-downs, sintering, and hot spots leading to corrosion and eventual failure of the reactor wall.

In addition, most of these process efforts included use of a fixed bed reactor on the basis of applicability of coal gasification is also applicable to waste. The most common equipment was a shaft reactor with a bottom temperature of approximately 1,000°C (1,830°F) leading to transport problems within the reactor bed and in the shaft to the ash outlet, such as ash sintering. The character of coal ash and its effect on gasification are well understood. The effect of ash from waste is not yet fully understood and requires extra effort before a suitable reactor can be proposed for waste gasification.

Finally, most of the systems proposed for waste gasification produced tar or a mixture of tar and gas and very few of the processes included gas cleaning. Thus, the tar-rich gas caused problems on the gas side as well as tar condensation in the pipes to the combustor. On the other hand, waste that contained metals, glass, and inorganic materials which sinter and melt at higher temperatures also caused reactor problems.

Overall, the heterogeneous composition of domestic and industrial waste has not been beneficial in terms of the gasification of the waste. Recycling programs in which the first is first separated into various components may be a necessary prelude to waste gasification. With energy prices (crude oil and natural gas) currently at an all-time high, and threatening to continue at high levels for the foreseeable future, the time is now for the development of waste gasification processes.

Liquid Fuels

Using ethanol as the example, numerous waste streams could be exploited for ethanol production. Some waste streams currently under consideration include mixed paper from municipal solid waste, cellulosic fiber fines from recycled paper mills, as well as various bio-feedstocks. However, each waste stream has its own unique characteristics, and they generally vary from one source or time to another. Therefore, ethanol or, for that matter, the production of liquid fuels from waste streams is not only feedstock dependent but is also process dependent.

Using the term loosely, the standard way of preparing liquid fuels from carbonaceous material is (i) to gasify the feedstock to produce synthesis gas and then (ii) convert the synthesis gas by the Fischer-Tropsch reaction to hydrocarbon derivatives. Briefly, synthesis gas (syngas) is the name given to a gas mixture that contains varying amounts of carbon monoxide and hydrogen generated by the gasification of a carbonaceous fuel to a gaseous product with a heating value. Examples include steam reforming of natural gas or liquid hydrocarbon derivatives to produce hydrogen, the gasification of coal, and in some types of waste-to-energy gasification facilities.

Synthesis gas consists primarily of carbon monoxide and hydrogen, with small amounts of carbon dioxide present in the raw (unpurified) gas carbon dioxide, and hydrogen and has less than half the energy density of natural gas. Synthesis gas is combustible and often used as a fuel source or as an intermediate for the production of other chemicals. Synthesis gas for use as a fuel is most often produced by gasification of coal or municipal waste mainly by the following paths:

When used as an intermediate in the large scale, industrial synthesis of hydrogen and ammonia, it is also produced from natural gas (via the steam reforming reaction) as follows:

The Fischer-Tropsch synthesis is, in principle, a carbon chain building process, where methylene groups are attached to the carbon chain. The actual reactions that occur have been, and remain, a matter of controversy, as it has been in the last century since 1930s.

Even though the overall Fischer-Tropsch process is described by the following simple chemical equation:

The initial reactants in the above reaction (i.e., CO and H₂) can be produced by other reactions such as the partial combustion of a hydrocarbon derivative:

For example (when $n = 1$), methane (in the case of gas-to-liquids applications):

Or by the gasification of any carbonaceous source, such as biomass and, in the current context, carbonaceous waste:

The energy needed for this endothermic reaction is usually provided by (exothermic) combustion with air or oxygen:

A modification of this concept involves the proposed addition of addition of hydrogen from a carbon-free energy source, such as solar or nuclear power, during the gasification step. The theoretical concept is a hybrid process insofar as liquid hydrocarbon fuels are proposed to be produced from biomass wherein biomass is the carbon source and hydrogen is supplied from carbon-free energy. The modeling of this biomass-to-liquids process indicates that the concept has the potential to provide the transportation sector for the foreseeable future, using the existing infrastructure.

In addition, although not mentioned because the concept is modeled on the complete gasification of the feedstock, the addition of hydrogen will not only suppress the formation of carbon dioxide but also the formation of other by-products, thereby increasing the efficiency of the process. The presence of hydrogen will also reduce the amount of char and tarry by-products which is in complete agreement with the observed beneficial effect of hydroprocesses in crude oil refineries has been known for decades. The hydrogen and energy balance may be even better if water (also produced during gasification) could be used as the hydrogen source.

The pyrolysis of waste tires is also a source of liquid fuels; the process by which this is achieved is often called *thermal depolymerization*. This term, however, is more of a term of convenience since it is rare that depolymerization, in the true scientific sense, actually occurs. Thermal depolymerization (TDP) is a term that is used to describe the reduction of complex organic materials into lower-molecular-weight products. Nevertheless, in this context, thermal cracking and catalytic cracking as used in the crude oil industry are examples of thermal depolymerization. The feedstocks for such processes may also include non-oil-based waste products, such as old tires, offal, wood, and plastic. However, the so-called thermal depolymerization process does not in any way mimic the natural geological processes thought to be involved in the production of fossil fuels, such as crude oil and natural gas.

In the thermal depolymerization process, conversion efficiencies can be high but are feedstock dependent. Quantifying the potential amount of product (e.g., biodiesel) can be done on a feedstock carbon vs. product carbon basis, but such estimates are only approximate.

Quantifying the amount of oil which could be produced from tire pyrolysis can be done in a similar manner to quantifying the amount of biodiesel produced from waste vegetable oil. It is simply a case of equating the amount of waste product available to the production yields. In the case of tire pyrolysis, the number of used tires produced each year is well documented. What is less certain, however, is the amount of suitable road transport oil that can be yielded from the pyrolysis process itself.

Another source of waste for the production of liquid fuels is waste cooking oil; usually, biodiesel is the desired product. In fact, waste cooking oil is a valuable asset for conversion to liquid fuels and the quantity of biodiesel which could be produced from waste cooking oil can be quantified in a manner similar to that of biodiesel produced direct from agriculture. The only difference is that rather than calculating crop yields, it is necessary to quantify the amount of waste oil available.

Biodiesel is a light-colored-to-dark-yellow-colored liquid that is immiscible with water and has a high boiling point and low vapor pressure. Typical methyl ester biodiesel has a flash point of approximately 150°C (300°F), making it non-flammable. Biodiesel has a density of 0.88 g/cm³. Biodiesel has a viscosity similar to crude oil-derived diesel (also known as petrodiesel, which is the current term to differentiate the different forms of diesel) and can be used as an additive in formulations of diesel to increase the lubricity of ultra-low sulfur diesel (ULSD) fuel. Much of the world uses a system known as the “B” factor to state the amount of biodiesel in any fuel mix – for example, fuel containing 20% v/v biodiesel is labeled B20 whereas pure biodiesel is referred to as B100.

Biodiesel is a renewable fuel that can be manufactured from algae, vegetable oils, animal fats, or recycled restaurant greases; it can be produced locally in most countries. It is safe, biodegradable, and reduces air pollutants, such as particulates, carbon monoxide, and hydrocarbon derivatives. Blends of 20% biodiesel with 80% crude oil-based diesel (B20) can generally be used in unmodified diesel engines. Biodiesel can also be used in its pure form (B100), but may require certain engine modifications to avoid maintenance and performance problems. Biodiesel is an alternative to crude oil-based diesel, but it is produced from biodegradable materials and can be used as fuel in diesel engines. It can also be used in boilers or furnaces designed to use heating oils or in oil-fueled lighting equipment or used neat (100% v/v biodiesel), or it can be blended with crude oil diesel.

Biodiesel is made by chemically reacting vegetable oil or animal fat (or combinations of oils and fats) with alcohol (usually nearly pure methanol or ethanol) and a catalyst (sodium hydroxide). The chemical reaction converts constituents of the vegetable oil into an ester (*biodiesel fuel*) and glycerol. Since the biodiesel is less dense than the glycerol, it floats on top of the glycerol and may be pumped off, or the glycerol can be drained off the bottom. The fuel can then be filtered and used in heating or lighting applications. It is possible to use the product in diesel engines without further processing, but caution is advised because of the potential for engine damage and it is recommended that impurities (unreacted alcohol and sodium hydroxide) are removed by washing.

Almost any variety of oil or grease (from new food-grade vegetable oil to used cooking oil or trap grease to wastewater treatment-plant grease) can be converted turned into biodiesel. However, the amounts of reactants (oil, methanol, and sodium hydroxide) vary to some degree, depending on what oil is used. The amount of methanol and sodium hydroxide must be sufficient to react with the vegetable oil, but excessive amounts of these reactants should not be used. Just as an engine requires excess air to be sure that all the fuel burns, it takes excess methanol to be sure all of the oil reacts.

The chemistry of biodiesel production (transesterification) involves the reaction of a glyceride-containing plant oil with a short chain alcohol such as methanol or ethanol:

Animal and plant fats and oils are typically made of triglyceride derivatives which are esters of free fatty acids with the trihydric alcohol, glycerol. In the transesterification reaction, the alcohol is deprotonated with a base to make it a stronger nucleophile. Commonly, ethanol or methanol is used. Usually, this reaction will proceed either exceedingly slowly or not at all. Heat, as well as an acid or base, is used to help the reaction proceed more quickly.

Almost all biodiesel is produced using the base-catalyzed technique as it is the most economical process requiring only low temperatures and pressures and producing over 98% conversion (provided the starting oil is low in moisture and free fatty acids). The major steps required to synthesize biodiesel are: (i) purification, (ii) neutralization, (iii) transesterification, and (iv) workup.

In the purification step, if waste vegetable oil is used, it is filtered to remove dirt, charred food, and other non-oil material often found. Water is removed because its presence causes the triglycerides to hydrolyze to give salts of the fatty acids instead of undergoing transesterification to give biodiesel. The crude oil may be stirred with a drying agent such as magnesium sulfate to remove the water in the form of water of crystallization. The drying agent can be separated by decanting or by filtration, but the viscosity of the oil may not allow the drying agent to mix thoroughly.

The neutralization step is the removal of free fatty acids: A sample of the cleaned oil is titrated against a standard solution of base in order to determine the concentration of free fatty acids (RCOOH) present in the waste vegetable oil sample. The quantity (in moles) of base required to neutralize the acid is then calculated.

The transesterification step is the addition of bases in which a slight excess of the base is factored in to provide the catalyst for the transesterification. The calculated quantity of base (usually sodium hydroxide) is added slowly to the alcohol, and it is stirred until it dissolves. Sufficient alcohol is added to make up three full equivalents of the triglyceride, and an excess is added to drive the reaction to completion. The solution of sodium hydroxide in the alcohol is then added to a warm solution of the waste oil, and the mixture is heated (typically 50°C) for several hours (4 to 8

typically) to allow the transesterification to proceed. A condenser may be used to prevent the evaporative losses of the alcohol. Care must be taken not to create a closed system which can explode.

Once the reaction is complete, workup begins. The glycerol should sink, but when ethanol is used, it is reported that an emulsion often forms. This emulsion can be broken by standing, centrifugation, or the addition of a low-boiling (easily removed) non-polar solvent, decanting, and distilling. The top layer, a mixture of biodiesel and alcohol, is decanted. The excess alcohol can be distilled off, or it can be extracted with water. If the latter, the biodiesel should be dried by distillation or with a drying agent.

Ethanol is produced from organic feedstocks, such as biomass, by a fermentation process. However, recent efforts have focused on the production of ethanol from waste materials using a gasification process. The overall process consists of a thermo-chemical conversion of synthesis gas which is then converted to higher-molecular-weight alcohols by a catalytic process after which high purity ethanol is separated by distillation. The process is similar to modern-day methanol and gas-to-liquids processes. The key differentiating factors are the catalysts and their operating parameters.

Most current research efforts have centered on bacteria, enzyme, and acid/solvent hydrolysis fermentation-based ethanol production. However, the action of bacteria and enzymes is often very dependent on the feedstock. In addition, these processes generate a small quantity of ethanol over a period of days and the dilute aqueous ethanol product must be distilled to recover the ethanol. In the gasification-synthesis process, various carbonaceous feedstocks can be used, with appropriate modifications in the syngas production step.

A new system for converting trash into ethanol and methanol could help reduce the amount of waste piling up in landfills while displacing a large fraction of the fossil fuels used to power vehicles in the United States. The technology developed does not incinerate refuse, so it does not produce the pollutants that have historically plagued efforts to convert waste into energy. Instead, the technology vaporizes organic materials to produce synthesis gas that can be used to synthesize a wide variety of fuels and chemicals. In addition to processing municipal waste, the technology can be used to create ethanol out of agricultural biomass waste, providing a potentially less expensive way to make ethanol than current corn-based plants.

The new system makes synthesis gas in two stages. In the first stage, waste is heated in a 1,200°C (2,190°F) chamber into which a controlled amount of oxygen is added to partially oxidize carbon and free hydrogen. Not all of the organic material is converted and some forms of char which is then gasified when researchers pass it through arcs of plasma. The remaining inorganic materials, including toxic substances, are oxidized and incorporated into a pool of molten glass which hardens into a material that can be used for building roads or discarded as a safe material in landfills. The second stage is a catalyst-based process for converting synthesis gas into equal ethanol and methanol.

It is fairly common knowledge that the alcohols other than methanol and ethanol can be made from organic materials by fermentation. There is, however, a potential for the production of alcohols from organic waste.

Historically, the production of methanol, ethanol, and higher molecular alcohols from syngas has been known since the beginning of the last century. There are several processes that can be used to make mixed alcohols from synthesis gas including iso-synthesis, variants of Fischer-Tropsch synthesis, oxo-synthesis involving the hydroformylation of olefins, and homologation of methanol and lower-molecular-weight alcohols to make higher alcohols. However, in the context of the Fischer-Tropsch process, depending on the process and its operating conditions, the most abundant products are usually methanol and carbon dioxide but methanol can be recycled to produce higher-molecular-weight alcohols.

With the development of various gas-to-liquids processes, there was general recognition that higher-molecular-weight (higher-boiling) alcohol derivatives were by-products of these processes when catalysts or conditions were not optimized. Modified Fischer-Tropsch (or methanol synthesis) catalysts can be promoted with alkali metals to shift the products toward higher alcohols. Synthesis of higher-molecular-weight alcohols is optimal at higher

temperatures and lower space velocities compared to methanol synthesis and with a hydrogen/carbon monoxide ratio of approximately 1 rather than 2 or greater.

The first step in the synthesis to ethanol and higher alcohols is the formation of a carbon-carbon bond. Linear alcohols are then produced in stepwise fashion:

Stoichiometry suggests that the carbon monoxide/hydrogen ratio is optimum at 2, but the simultaneous presence of water-gas shift leads to an optimum ratio closer to 1.

As in other synthesis gas conversion processes, the synthesis of higher-molecular-weight alcohols generates significant heat, and an important aspect is choice of the proper reactor to maintain even temperature control which then maintains catalyst activity and selectivity. In fact, the synthesis of higher-molecular-weight alcohols is carried out in reactors similar to those used in methanol and Fischer-Tropsch synthesis. These include shell and tube reactors with shell-side cooling, trickle-bed, and slurry bed reactors.

Catalysts for the synthesis of higher-molecular-weight alcohols generally fall mainly into four groups: (i) modified high-pressure methanol synthesis catalysts, such as alkali-doped $\text{ZnO/Cr}_2\text{O}_3$, (ii) modified low-pressure methanol catalysts, such as alkali-doped Cu/ZnO and $\text{Cu/ZnO/Al}_2\text{O}_3$, (iii) modified Fischer-Tropsch catalysts, such as alkali-doped $\text{CuO/CoO/Al}_2\text{O}_3$, and (iv) alkali-doped sulfides, such as mainly molybdenum sulfide (MoS_2).

In the process, the feedstock enters the process and is converted to synthesis gas with the desired carbon monoxide/hydrogen ratio, which is then reacted, in the presence of a catalyst, into methanol (CH_3OH), ethanol ($\text{CH}_3\text{CH}_2\text{OH}$), and higher-molecular-weight alcohols.

The catalytic synthesis process makes several different alcohols depending, in part, on residence time in the reactor and the nature of the catalyst. The alcohols can be separated by distillation and dried to remove water.

Another aspect of this concept is to produce the alcohols by a catalytic method in which the catalyst is in the form of unsupported nano-sized particles or supported on a high surface area support such as carbon, alumina, or silica (Mahajan and Jackson, 2004). In either arrangement, the nano-sized catalyst is suspended in an inert solvent, such as a high-molecular-weight hydrocarbon solvent, to form a slurry. The synthesis gas is then passed through the catalyst slurry to produce alcohols in the product stream. The operating temperature range is from 200°C to 300°C at a pressure ranges from 500 to 3,000 psi.

A further aspect of the waste-to-alcohols concept is the use of a plasma field (<http://www.fuelfrontiers.com/technology.htm>) in which temperatures are reputed (but not yet proved) to reach 30,000°C (54,000°F). The feedstock can be materials such as waste coal, used tires, wood wastes, raw sewage, municipal solid wastes, biomass, discarded roofing shingles, coal waste (*culm*), and discarded corn stalks. The plasma field breaks down the feedstock into their core elements in a clean and efficient manner.

Solid Fuels

The use of organic waste as cooking fuel in both rural and urban areas is not new. In 17th century England, the rural poor often burned dried cow dung because of the acute shortage of wood fuel due to widespread deforestation. In some countries, cattle and buffalo dung is still used as relatively good cooking fuel. In the beginning of the nineteenth century, sawdust briquettes were made with binding materials such as tar, resins, and clay bind the small particles together. None of these processes attained great importance because of their relatively high costs compared to wood and conventional charcoal fuels.

Fuel briquettes emerged as a significant business enterprise in the 20th century. In the 1950s, several economic methods were developed to make briquettes without a binder. A multitude of factories throughout the world produced literally tens of millions of tons of usable and economic material that met the household and industrial energy

needs. During the two World Wars, households in many European countries made their own briquettes from soaked waste paper and other combustible domestic waste using simple lever-operated presses. Modern industrial briquetting machines, although much larger and more complex, operate on the same principle, and a variety of solid fuels are available.

For over 100 years, informal waste collectors in Cairo have separated and dried organic waste products for sale as solid fuel for domestic use. This process faded somewhat when fossil fuel sources became available. Switching to conventional fuels may prove advantageous to those who can afford them, but given the economic and energy conditions in many cities, urban and agricultural wastes remain a viable alternative fuel.

Briquetting is undergoing resurgence, principally due to the convergence of three critical factors. First, the recent developments in briquette processing and binding have dramatically changed the economics of using fuel briquettes as an energy resource. Secondly, a shortage of fuel wood has become increasingly severe in most of the developing countries. Finally, there has been a steady increase by environmental concerns to address the problem of domestic and urban waste disposal, a dilemma that briquetting can help remedy.

Generally, briquette manufacture (*briquetting*) involves the collection of combustible materials that are not usable as such because of their low density, and compressing them into a solid fuel product of any convenient shape that can be burned like wood or charcoal. Thus, the material is compressed to form a product of higher bulk density, lower moisture content, and uniform size, shape, and material properties. Briquettes are easier to package and store, cheaper to transport, more convenient to use, and their burning characteristics are better than those of the original organic waste material.

The raw material of a briquette must bind during compression; otherwise, when the briquette is removed from the mold, it will crumble. Improved cohesion can be obtained with a binder but also without, since under high temperature and pressure, some materials such as wood bind naturally. A binder must not cause smoke or gummy deposits, while the creation of excess dust must also be avoided. Two different sorts of binders may be employed. Combustible binders are prepared from natural or synthetic resins, animal manure, or treated, dewatered sewage sludge. Non-combustible binders include clay, cement, and other adhesive minerals. Although combustible binders are preferable, non-combustible binders may be suitable if used in sufficiently low concentrations. For example, if organic waste is mixed with too much clay, the briquettes will not easily ignite or burn uniformly. Suitable binders include starch (5 to 10% w/w) or molasses (15 to 25% w/w) although their use can prove expensive (Lardinois and Klundert, 1993). It is important to identify additional, inexpensive materials to serve as briquette binders in Kenya and their optimum concentrations. The exact method of preparation depends upon the material being briquetted as illustrated in the following three cases of compressing sugar bagasse, sawdust, and urban waste into cooking briquettes.

Surplus bagasse presents a disposal problem for many sugar factories. Briquetting technology remains simple, and involves the following steps: (i) size reduction in which the bagasse is chopped, rolling, or hammered, (ii) drying in which moisture is removed by open air drying or by using forced, heated air in a large rotating drum, (iii) carbonization in which the bagasse is combusted in a limited supply of oxygen in a buried pit or trench until it carbonizes into charcoal, (iv) feedstock preparation in which the carbonized bagasse is mixed with a binder such as clay or molasses, (v) compaction and extrusion in which the material is passed through a machine-operated or manually-operated extruder to form *rolls* of charcoal, (vi) drying in which the rolls are air-dried for 1 to 3 days, causing them to break into chunks, and (vii) packaging in which the briquettes are made ready for sales.

Sawdust is waste material from all types of primary and secondary wood processing. Between 10 and 13% w/w of a log is reduced to sawdust in milling operations. Sawdust is bulky, and is therefore expensive to store and transport. Also, the calorific value of sawdust is quite low, so that briquetting is an ideal way to reduce the bulk, to increase the density, and thus to increase the calorific value. The equipment required for producing sawdust briquettes consist of a drier, a press, and an extruder with a tapered screw and a large revolving disk.

Sawdust briquettes are formed under sufficiently high pressure to produce cohesion between wood particles. In the process, the lignin softens and binds the briquette, so no additional binder is required. The use of sawdust briquettes has several advantages, including (i) price which is usually approximately the same as fuel wood but is much more convenient to use as they do not require further cutting and chopping, (ii) good burning characteristics in any kind of solid fuel stove and boiler, (iii) quick ignition followed by clean burning and only leaving 1% to 6% w/w ash, (iv) sulfur-free and burn without producing an odor, and (v) a heat content of approximately 18,000 KJ/kgm which is almost equivalent to the heat content of medium-quality coal.

Solid waste disposal is one of the most serious urban environmental problems in developing countries. Many municipal authorities collect and adequately dispose (in places other than landfill sites) less than half of these wastes. This failure is attributed to (i) an inadequate number of landfill sites, (ii) a variety of environmental regulations, (iii) the absence of sufficient capacity for waste processing and recycling, and last, but not least, (iv) the planned obsolescence of packaging and many of the items that form the basis of the waste.

Open or crude dumping is the most common method used by municipal authorities. Waste poses a health hazard when it lies scattered in the streets and at the dumping sites. It is now an accepted environmental philosophy that wastes have value and should be utilized based on principles of *reduce, reuse, recover*, and *recycle*. Through recycling, urban wastes can be transformed into useful products. Waste paper and leaves, in particular, provide a potentially important, alternative source of cooking fuel.

Waste – Hazardous

The types of hazardous wastes consist of solid, liquid, and gaseous streams and can be further classified as: (i) inorganic or organic waste, (ii) metal or non-metal waste, (iii) aqueous or non-aqueous waste, (iv) halogenated or non-halogenated waste, (v) ignitable or non-ignitable waste, (vi) corrosive or non-corrosive waste, (vii) reactive or non-reactive waste, and (viii) toxic or non-toxic waste.

Many hazardous materials can display more than one of the above properties, and their waste streams become more complex through mixing and contamination as they pass further from the place at which they were generated. It is much simpler to recover materials for reuse when they have not been cross-contaminated with other hazardous wastes or for that matter any other wastes. Therefore, it is usually desirable to set up, recovery, and recycling equipment as near the waste generation site as possible and in any case to segregate waste streams to prevent cross-contamination.

Some waste streams are clearly not compatible and should not be mixed unless special safety precautions have been taken to protect against the hazards generated by the mixing. An example of such incompatible waste streams is provided by an aqueous acid stream and a second stream containing either soluble sulfides or cyanides. Mixing would generate extremely toxic hydrogen cyanide (HCN) gas or hydrogen sulfide (H_2S) gas. Such incompatible waste streams usually involve corrosive or reactive wastes as one of the waste streams.

Waste separation processes are classified as (i) homogeneous processes or (ii) heterogeneous processes.

Many waste streams are homogeneous and require more complex processes such as distillation, extraction, and adsorption for recovery of valuable materials. On the other hand, heterogeneous wastes are usually relatively easy to separate into their respective phases, as is often the case with oily wastewaters, and the recovery of valuable materials can be quite convenient by the use of coalescing and settling devices.

The hazardous contaminants waste gas streams can be gases, liquids, or solids and must be removed from the gas stream prior to discharge to the atmosphere. Typical examples of hazardous gases are toxic materials such as carbon monoxide (CO), hydrogen sulfide (H_2S), and hydrogen cyanide (HCN), as well as environmentally undesirable gases such as oxides of nitrogen (NOx) and oxides of sulfur (SOx) as well as vapors from hazardous liquids such as paint solvents, gasoline, and halogenated cleaning solvents.

The liquids in gases are generally in the form of mists or fogs either caused by entrainment from gas-liquid contacting or by condensation of vapors in the gas stream due to cooling. The separation of mists and fogs requires coalescence of the liquid droplets into larger drops that can be more readily removed from the gas phase by settling.

Finally, the solids are usually in the form of dusts entrained in the gas stream and exist in the gas stream as a second phase, as with liquids in gases, they are also separated by mechanical techniques. Large particles can be readily settled out of a gas phase, but dust-like particles generally require some form of mechanical help. This mechanical help can take the form of cyclones, filters, scrubbers, or electrostatic precipitators, and all are in common use.

When gases exist as a separate phase in liquids, they can usually be recovered by coalescing the entrained gas bubbles into large bubbles and letting them settle out of the liquid phase. If necessary, the viscosity of the continuous liquid phase can be reduced by heating to improve both coalescing and settling. On the other hand, if the gases are dissolved in the liquid phase, some sort of carrier phase must be generated to strip the dissolved gases out of the liquid. This can be an inert gas, such as steam, air, carbon dioxide, or nitrogen, blown through the liquid phase as a stripping gas in a stripping column. Alternatively,

vapors generated from the liquid by heating it to a boil as in flash distillation can be used to strip out gases. In this latter case, the stripping gases are the vapors generated by the boiling liquid.

As with gaseous contaminants, liquid contaminants can also exist in liquid systems as either a separate liquid phase or as a homogeneous solution. When a heterogeneous system is encountered, the recovery processes are mechanical in nature such as settling, flotation, coalescing, cycloning, and centrifuging. On the other hand, if the system is homogeneous, either equilibrium- or rate-controlled processes must be used. The equilibrium processes are distillation, stripping, adsorption, extraction and supercritical extraction, ion exchange, and solvent precipitation.

Solid contaminants can also exist in liquids either as slurries or in the dissolved e. As with other heterogeneous systems, the slurries are separated by mechanical techniques such as settling, filtration, flocculation, flotation, centrifuging, and drying. With the homogeneous systems, evaporation and crystallization are frequently used to generate a heterogeneous system followed by one of the techniques for heterogeneous systems.

Solids can be contaminated with relatively small amounts of adsorbed gases liquids as with spent adsorbents, or with larger amounts of liquids as with cakes and sludges. Furthermore, solids can absorb either liquids or gases give swollen solids and gels. Solid polymers can show this latter behavior, and solids can exist as mixtures with other solids as in the case of many domestic and industrial solid wastes.

Most of the separation processes encountered in hazardous waste management involve processes such as batch distillation, adsorption, settling, and filtration which can be operated efficiently over a wide range of operating parameters. It is important to have this capability, particularly for continuous processes such as wastewater treating and stack gas scrubbing where flow rates change in response to manufacturing operations.

Waste to Energy

Waste to energy (WTE or WtE or Energy from Waste, EfW) is the term used to describe the conversion of waste by-products into useful steam or steam-generated electricity. Typically, waste-to-energy is produced by converting municipal solid waste (MSW), which is defined as residential and commercial refuse, and makes up the largest source of waste in industrialized countries. This industry has been producing heat and power in the United States for a century, and there are currently in excess of one hundred waste-to-energy plants nationwide. Recently, however, the definition of waste has been expanded from municipal solid waste to include wastes such as wood, wood waste, peat, wood sludge, agricultural waste, straw, tires, landfill gases, fish oils, paper industry liquors, railroad ties, and utility poles.

Most waste-to-energy processes produce electricity and/or heat directly through combustion, or produce a combustible fuel commodity, such as methane (CH_4), methanol (CH_3OH), ethanol ($\text{C}_2\text{H}_5\text{OH}$), or synthetic fuels. The generation of energy by the use of many forms of waste can make a significant contribution to a national renewable energy. For example, incineration, the combustion of organic material such as waste with energy recovery, is the most common waste-to-energy implementation. Modern incineration plants are vastly different from old types, some of which neither recovered energy nor materials. Modern incinerators reduce the volume of the original waste by 95 to 96%, depending upon composition and degree of recovery of materials such as metals from the ash for recycling.

Generally, waste-to-energy facilities can be divided into two process types: (i) mass burn and (ii) refuse-derived fuel (RDF). Mass burn facilities process raw waste that has not been shredded, sized, or separated before combustion, although large items such as appliances and hazardous waste materials and batteries are removed before combustion. In mass burn systems, untreated municipal solid waste is combusted burned, with the heat produced converted into steam, which can then be passed through a steam turbine to generate electricity or used directly to supply heat to nearby industries or buildings.

Refuse derived fuel is a result of processing municipal solid waste to separate the combustible fraction from the non-combustible constituents, such as metals and glass. Refuse-derived fuel is mainly composed of paper, plastic, wood, and kitchen or yard wastes, and has a higher energy content than untreated municipal solid waste, and, like municipal solid waste, the refuse-derived fuel is then burned to produce steam and/or electricity. A benefit of using refuse-derived fuel is that it can be shredded into uniformly sized particles or compressed into briquettes, both of

which facilitate handling, transportation, and combustion. Another benefit of refuse-derived fuel rather than raw municipal solid fuels is that fewer non-combustible constituents such as heavy metals are burned.

The benefits of converting waste to energy include the following: (i) preventing the release of greenhouse gases such as methane into the atmosphere which would occur if the waste was sent to a landfill site, (ii) reducing the impact on landfill sites by reducing the volume of the waste 80 to 90%, (iii) providing an alternative to coal use, which prevents the release of emissions such as nitrogen oxides into the atmosphere, and (iv) saving the natural resources of the Earth by using less natural gas, crude oil, or coal for electricity generation.

Among the criticisms of the generation of energy via many wastes (even including biomass waste), biomass waste is the emission of fine particulate matter. Incineration of waste in general also has the complications of emission of heavy metals, trace dioxin, and acid gas, and critics argue that incinerators destroy valuable resources and they may reduce incentives for recycling.

Waste – Toxicity

With few exceptions, the constituents of petroleum, petroleum products, and the various emissions are hazardous to health. There are always exceptions that will be cited in opposition to such a statement, the most common exception being the liquid paraffin that is used medicinally to lubricate the alimentary tract. The use of such medication is common among miners who breathe and swallow coal dust every day during their work shifts.

Another approach is to consider petroleum constituents in terms of transportable materials, the character of which is determined by several chemical and physical properties (i.e., solubility, vapor pressure, and propensity to bind with soil and organic particles). These properties are the basis of measures of leachability and volatility of individual hydrocarbons. Thus, petroleum transport fractions can be considered by equivalent carbon number to be grouped into thirteen different fractions. The analytical fractions are then set to match these transport fractions, using specific *n*-alkanes to mark the analytical results for aliphatic compounds and selected aromatic compounds to delineate hydrocarbons containing benzene rings.

Although chemicals grouped by transport fraction generally have similar toxicological properties, this is not always the case. For example, benzene is a carcinogen but many alkyl-substituted benzenes do not fall under this classification. However, it is more appropriate to group benzene with compounds that have similar environmental transport properties than to group it with other carcinogens such as benzo(a)pyrene that have different environmental transport properties.

Nevertheless, the consultation of any reference work that lists the properties of chemicals will show the properties and hazardous nature of the types of chemicals that are found in petroleum. In addition, petroleum is used to make petroleum products, which can contaminate the environment.

The range of chemicals in petroleum and petroleum products is so vast that summarizing the properties and/or the toxicity or general hazard of petroleum in general or even for a specific crude oil is a difficult task. However, petroleum and some petroleum products, because of the hydrocarbon content, are at least theoretically biodegradable, but large-scale spills can overwhelm the ability of the ecosystem to break the oil down. The toxicological implications from petroleum occur primarily from exposure to or biological metabolism of aromatic structures. These implications change as an oil spill ages or is weathered.

Air emissions include point and non-point sources. Point sources are emissions that exit stacks and flares and, thus, can be monitored and treated. Non-point sources are fugitive emissions which are difficult to locate and capture. Fugitive emissions occur throughout refineries and arise from the thousands of valves, pumps, tanks, pressure relief valves, and flanges. While individual leaks are typically small, the sum of all fugitive leaks at a refinery can be one of its largest emission sources.

The numerous process heaters used in refineries to heat process streams or to generate steam (boilers) for heating or steam stripping, can be potential sources of SO_x, NO_x, CO, particulates, and hydrocarbon emissions. When operating properly and when burning cleaner fuels such as refinery fuel gas, fuel oil, or natural gas, these emissions are relatively low. If, however, combustion is not complete, or heaters are fired with refinery fuel pitch or residuals, emissions can be significant.

The majority of gas streams exiting each refinery process contain varying amounts of refinery fuel gas, hydrogen sulfide, and ammonia. These streams are collected and sent to the gas treatment and sulfur recovery units to recover the refinery fuel gas and sulfur. Emissions from the sulfur recovery unit typically contain some H_2S , SO_x , and NO_x . Other emission sources from refinery processes arise from periodic regeneration of catalysts. These processes generate streams that may contain relatively high levels of carbon monoxide, particulates, and volatile organic compounds (VOCs). Before being discharged to the atmosphere, such off-gas streams may be treated first through a carbon monoxide boiler to burn carbon monoxide and any volatile organic compounds, and then through an electrostatic precipitator or cyclone separator to remove particulates.

Sulfur is removed from a number of refinery process off-gas streams (sour gas) in order to meet the SO_x emissions limits of the United States Clean Air Act and to recover saleable elemental sulfur. Process off-gas streams, or sour gas, from the coker, catalytic cracking unit, hydrotreating units, and hydroprocessing units can contain high concentrations of hydrogen sulfide mixed with light refinery fuel gases. Before elemental sulfur can be recovered, the fuel gases (primarily methane and ethane) need to be separated from the hydrogen sulfide. This is typically accomplished by dissolving the hydrogen sulfide in a chemical solvent. The solvents most commonly used are amines, such as diethanolamine (DEA). Dry adsorbents such as molecular sieves, activated carbon, iron sponge, and zinc oxide are also used. In the amine solvent processes, DEA solution or another amine solvent is pumped to an absorption tower where the gases are contacted and hydrogen sulfide is dissolved in the solution. The fuel gases are removed for use as fuel in process furnaces in other refinery operations. The amine-hydrogen sulfide solution is then heated and steam stripped to remove the hydrogen sulfide gas.

The current methods for removing sulfur from the hydrogen sulfide gas streams are typically a combination of two processes: the Claus Process followed by the Beavon Process, SCOT Process, or the Wellman-Lord Process. The Claus process consists of partial combustion of the hydrogen sulfide-rich gas stream (with one-third the stoichiometric quantity of air) and then reacting the resulting sulfur dioxide and unburned hydrogen sulfide in the presence of a bauxite catalyst to produce elemental sulfur.

Most refinery process units and equipment are sent to a collection unit called the blowdown system. Blowdown systems provide for the safe handling and disposal of liquid and gases that are either automatically vented from the process units through pressure relief valves, or that are manually drawn from units. Recirculated process streams and cooling water streams are often manually purged to prevent the continued buildup of contaminants in the stream. Part or all of the contents of equipment can also be purged to the blowdown system prior to shut down before normal or emergency shutdowns. Blowdown systems utilize a series of flash drums and condensers to separate the blowdown into its vapor and liquid components. The liquid is typically composed of mixtures of water and hydrocarbons containing sulfides, ammonia, and other contaminants, which are sent to the wastewater treatment plant. The gaseous component typically contains hydrocarbons, hydrogen sulfide, ammonia, mercaptans, solvents, and other constituents, and is either discharged directly to the atmosphere or is combusted in a flare. The major air emissions from blowdown systems are hydrocarbons in the case of direct discharge to the atmosphere and sulfur oxides when flared.

Many of the gaseous and liquid constituents of the lower-boiling fractions of petroleum and also in petroleum products fall into the class of chemicals which have the one or more of the following characteristics are considered to be hazardous by the Environmental Protection agency in terms of the following properties (i) ignitability-flammability, (ii) corrosivity, (iii) reactivity, and (iv) hazardous.

Waste – Types

Waste types associated with petroleum refining typically include VOCs (volatile organic compounds), carbon monoxide (CO), sulfur oxides (SO_x), nitrogen oxides (NO_x), particulates, ammonia (NH_3), hydrogen sulfide (H_2S), metals, spent acids, and numerous toxic organic compounds. Sulfur and metals result from the impurities in crude oil. The other wastes represent losses of inputs and final product. These pollutants may be discharged as air emissions, waste water, or solid waste. All of these wastes are treated. However, air emissions are more difficult to capture than wastewater or solid waste. Thus, air emissions are the largest source of untreated wastes released to the environment.

More specifically to petroleum and petroleum products, the alkanes in gasoline and some other petroleum products are CNS depressants. In fact, gasoline was once evaluated as an anesthetic agent. However, sudden deaths, possibly as a result of irregular heartbeats, have been attributed to those inhaling vapors of hydrocarbons such as those in gasoline.

Alkanes of various types of crude oils and various petroleum products were biodegraded faster than the *unresolved fractions*. Different types of crude oils and products are biodegraded at different rates in the same environments. An oil product is a complex mixture of organic chemicals and contains within it less persistent and more persistent fractions. The range between these two extremes is greatest for crude oils. Since the many different substances in petroleum have different physical and chemical properties, summarizing the fate of petroleum in general (or even a particular oil) is difficult. Solubility-fate relationships must be considered.

The relative proportion of hazardous constituents present in petroleum is typically quite variable. Therefore, contamination will vary from one site to another. In addition, the farther one progresses from lighter toward heavier constituents (the general progression from lower-molecular-weight to higher-molecular-weight constituents), the greater the percentage of polynuclear aromatic hydrocarbons and other semi-volatile constituents or non-volatile constituents (many of which are not so immediately toxic as the volatiles but which can result in long-term/chronic impacts). These higher-molecular-weight constituents thus need to be analyzed for the semi-volatile compounds that typically pose the greatest long-term risk.

In addition to large oil spills, petroleum hydrocarbons are released into the aquatic environments from natural seeps as well as non-point source urban runoffs. Acute impacts from massive one-time spills are obvious and substantial. The impacts from small spills and chronic releases are the subject of much speculation and continued research. Clearly, these inputs of petroleum hydrocarbons have the potential for significant environmental impacts, but the effects of chronic low-level discharges can be minimized by the net assimilative capacities of many ecosystems, resulting in little detectable environmental harm.

Short-term (acute) hazards of lighter, more volatile and water-soluble aromatic compounds (such as benzenes, toluene, and xylenes) include potential acute toxicity to aquatic life in the water column (especially in relatively confined areas) as well as potential inhalation hazards. However, the compounds which pass through the water column often tend to do so in small concentrations and/or for short periods of time, and fish and other pelagic or generally mobile species can often swim away to avoid impacts from spilled oil in open waters. Most fish are mobile, and it is not known whether or not they can sense, and thus avoid, toxic concentrations of oil.

However, there are some potential effects of spilled oil on fish. The impacts to fish are primarily to the eggs and larvae, with limited effects on the adults. The sensitivity varies by species; pink salmon fry are affected by exposure to water-soluble fractions of crude oil, while pink salmon eggs are very tolerant to benzene and water-soluble petroleum. The general effects are difficult to assess and quantitatively document due to the seasonal and natural variability of the species. Fish rapidly metabolize aromatic hydrocarbons due to their enzyme system.

Long-term (chronic) potential hazards of lighter, more volatile, and water-soluble aromatic compounds include contamination of groundwater. Chronic effects of benzene, toluene, and xylene include changes in the liver and harmful effects on the kidneys, heart, lungs, and nervous system.

At the initial stages of a release, when the benzene-derived compounds are present at their highest concentrations, acute toxic effects are more common than later. These non-carcinogenic effects include subtle changes in detoxifying enzymes and liver damage. Generally, the relative aquatic acute toxicity of petroleum will be the result of the fractional toxicities of the different hydrocarbons present in the aqueous phase. Tests indicate that naphthalene-derived chemicals have a similar effect.

Except for short-term hazards from concentrated spills, BTEX compounds (benzene, toluene, ethyl benzene, and xylenes) have been more frequently associated with risk to humans than with risk to non-human species such as fish and wildlife. This is partly because plants, fish, and birds take up only small amounts and because this volatile compound tends to evaporate into the atmosphere rather than persisting in surface waters or soils. However, volatiles such as this compound have can pose a drinking water hazard when they accumulate in ground water.

Petroleum is naturally weathered according to its physical and chemical properties, but during this process, living species within the local environment may be affected via one or more routes of exposure, including ingestion, inhalation, dermal contact, and, to a much lesser extent, bioconcentration through the food chain. Aromatic compounds of concern include alkylbenzenes, toluene, naphthalenes, and polynuclear aromatic hydrocarbons (PNAs).

Moreover, both atmospheric and hydrospheric impacts must be assessed when considering toxic implications from a petroleum release containing significant quantities of these single-ring aromatic compounds.

Waste Disposal

Given the large amounts of waste produced in modern society, there is an obvious need for technology to reduce the amount of waste that is land filled or, worse yet, improperly disposed.

Waste disposal techniques have created subtle and yet serious environmental pollution havoc in many developing countries. This has led to the degradation of abiotic and biotic components of ecological systems. Poor industrial waste disposal systems as well as the indiscriminate and inappropriate domestic litter disposal habit have been identified and proved to be basic features in rural settlements, semi-urban areas, and urban centers of the developing world. These have seriously contributed to environmental pollution and ecological deterioration.

The major reasons for these adverse effects were identified to be inadequate information and insufficient modern waste disposal facilities. As a result, the use of simple, yet efficient and environmentally benign disposal techniques are required.

Waste management solutions must be financially sustainable, technically feasible, socially, legally acceptable, and environmentally friendly. The conventional landfill, incineration, composting, and ways of handling wastes are common as mature technologies for waste disposal. Traditionally, the most commonly used technologies for the treatment and valorization of the organic fraction of waste are composting and anaerobic digestion. The generation of organic solid waste worldwide is dramatically increasing each year. Most of the organic solid wastes are composed of agricultural waste, household food waste, human and animal wastes, etc. They are normally handled as animal feed, incinerated or disposed to landfill sites. Organic solid wastes are comprised of materials rich in proteins, minerals, and sugars that could be used in other processes as substrates or raw materials.

The problem of waste disposal can be alleviated, to some extent, by a variety of methods, such as (alphabetically): (i) acid hydrolysis, (ii) anaerobic digestion, (iii) briquetting, (iv) enzymatic hydrolysis, (v) gasification, (vi) incineration, and (vii) pyrolysis.

Waste Disposal – Acid Hydrolysis

Acid hydrolysis is the means by which cellulosic material can be converted to lower-molecular-weight products and thence to fuels.

Enormous amounts of inexpensive and renewable lignocellulose waste are generated each year from forestry and agricultural production. These include fruit processing residues, dairy industry wastes, corn and sugar by-products, and paper industry wastes. Lignocellulosic biomass can be converted to biofuels such as ethanol and hydrogen via simple sugars. Lignocellulose is a composite of cellulose fibres embedded in a cross-linked lignin-hemicellulose matrix. It gives structure and strength to plants. Although abundant, lignocellulosic waste is difficult to convert to fermentable sugars because of its complex chemical structure: its three major components (cellulose – crystalline and amorphous – hemicellulose, and lignin) must be processed separately.

Cellulose consists of linear, highly ordered chains of glucose and is one of the most abundant biopolymers on the Earth. When produced by plants, it has both highly amorphous regions containing large voids and other irregularities as well as tightly packed crystalline regions. It also accumulates in the environment because it is resistant to most forms of degradation.

Hemicellulose is a complex polymer of a variety of sugar derivatives and consists predominantly of six-carbon and five-carbon sugar derivatives. Lignin is a poly-phenolic polymer that fills the spaces in the cell wall between cellulose, hemicellulose, and pectin components. It is covalently linked to hemicellulose and crosslinks different plant polysaccharides, conferring mechanical strength to the cell wall, and by extension, the plant as a whole.

Because lignocellulosic biomass is so complex, it is difficult to use as a feedstock for biofuel. A variety of physical, chemical, and enzymatic processes have been developed to fractionate lignocellulose into the major plant components of hemicellulose, cellulose, and lignin. Ethanol is produced from lignocellulose via pre-treatment, hydrolysis,

fermentation, and distillation (Figure 10.1). The goal of pre-treatment is to increase the surface area of lignocellulosic material, making the polysaccharides more susceptible to hydrolysis, by separating the xylose and lignin from the crystalline cellulose. Pre-treatment must also avoid the degradation or loss of precious carbohydrates and avoid the formation of by-products that can inhibit subsequent steps.

Steam explosion involves saturation of the pores of plant materials with steam followed by rapid decompression. The explosive expansion of steam reduces the plant material to separated fibers, increasing the accessibility of polysaccharides to subsequent hydrolysis. Ammonia fiber explosion (AFEX) is similar to steam explosion except that liquid ammonia is used. It is very effective on agricultural residues but has not been successful in pre-treating woody biomass.

The mechanisms by which pre-treatments improve the digestibility of lignocellulose are not well understood. Pre-treatment effectiveness has been correlated with the removal of hemicellulose and lignin (lignin solubilization is beneficial for subsequent hydrolysis but may also produce derivatives that inhibit enzyme activity). Some pre-treatments reduce the crystallinity of cellulose, which improves reactivity, but this does not appear to be the key for many successful pre-treatments.

Hydrolysis is the use of water molecules to fragment a molecule. Hemicellulose is readily hydrolyzed to pentoses (5 carbon sugars), but pentoses are difficult to ferment. The cellulose hydrolyzes to hexoses (6 carbon sugars). Crystalline cellulose is difficult to hydrolyze, but the resulting hexoses are readily fermented. The three basic methods for hydrolyzing structural polysaccharides to fermentable sugars (glucose, xylose, arabinose) are concentrated acid hydrolysis, dilute acid hydrolysis, and enzymatic hydrolysis.

Acid treatment is the use of acid to hydrolyze cellulosic materials. Two acid processes hydrolyze both hemicellulose and cellulose with very little pre-treatment beyond comminution of the lignocellulosic material to particles of approximately 1 mm in size. These are concentrated and dilute acid hydrolysis.

Concentrated acid hydrolysis dissolves carbohydrates in woody biomass to form a homogenous gelatine with acid where cellulose is extremely susceptible to hydrolysis. Typically, this is achieved with 70 to 90% w/w sulfuric acid at room temperature, leaving lignin. Before fermentation, the solution of oligosaccharides is diluted to 4% sulfuric acid and boiled for four hours or processed using an autoclave at 120°C (250°F) for one hour to yield monosaccharides. Following neutralization with limestone, the sugar solution is fermented – the procedure takes 10 to 12 hours. Concentrated acid hydrolysis is attractive because it is relatively simple, and high sugar yields (approach 100% w/w of theoretical hexose yields in pure samples and 90% w/w of the theoretical yield in mixed samples which replicate municipal waste mixtures) are achieved.

Dilute acid hydrolysis (1% v/v acid by weight) greatly reduces the amount of acid required to hydrolyze lignocellulose. The process is accelerated at elevated temperatures: 100 to 160°C (212 to 320°F) for hemicellulose and 180 to 220°C (355 to 430°F) for cellulose. The high temperatures cause oligosaccharides released from the lignocellulose to decompose, greatly reducing yields of simple sugars to only 55 to 60% w/w of the theoretical yield. The decomposition products include toxins – such as acetic acid, $\text{CH}_3\text{CO}_2\text{H}$, and furfural – which inhibit fermentation.

See also: Acid Hydrolysis.

Waste Disposal – Anaerobic Digestion

Anaerobic digestion (AD) focuses on hastening the natural process of biomass conversion to a gaseous fuel (biogas). Research has been conducted to ascertain optimal conditions for anaerobic digestion. These include (i) feedstock, (ii) nutrients, (iii) temperature, (iv) moisture, (v) pH, and (vi) atmospheric conditions. Most biomass waste feedstocks produce a biogas rich in methane. This medium to high Btu gas can, in some instances, be upgraded to a substitute natural gas (SNG). Depending on the feedstock, sulfur may also be produced.

During anaerobic digestion of biomass, a varied mixture of complex compounds is converted to a very narrow range of simple compounds, mainly methane and carbon dioxide. The anaerobic bacteria are responsible for the biochemical transformation of the biodegradable organic fraction (BOF). The AD of organic material basically consists of hydrolysis, acidogenesis, acetogenesis, and methanogenesis (Figure 10.4). These chemical transformations are involved in the breakdown of complex polymers, such as cellulose, fats, and proteins to long and short chain fatty acids, and finally to methane, carbon dioxide, and water.

Anaerobic digestion is a complex process which requires strict anaerobic conditions [oxidation reduction potential (ORP) < -200 mV] to proceed and depends on the coordinated activity of a complex microbial association to transform organic material into mostly carbon dioxide and methane. Despite the successive steps, hydrolysis is generally considered as rate limiting. The hydrolysis step degrades both insoluble organic material and high-molecular-weight compounds (lipids, polysaccharides, proteins, and nucleic acids) into soluble organic substances (amino acids and fatty acids). The components formed during hydrolysis are further split during acidogenesis, the second step. Volatile Fatty Acids (VFAs) are produced by acidogenic bacteria along with ammonia (NH_3), carbon dioxide (CO_2), hydrogen sulfide (H_2S), and other by-products. The 3rd stage in anaerobic digestion is *acetogenesis*, where the higher organic acids and alcohols produced by acidogenesis are further digested by acetogens to produce mainly acetic acid as well as carbon dioxide and hydrogen. The final stage of methanogenesis produces methane by two groups of methanogenic bacteria: the first group splits acetate into methane and carbon dioxide, and the second group uses H_2 as electron donor and carbon dioxide as acceptor to produce methane.

In a typical anaerobic digestion process, biomass is simply allowed to degrade in an anaerobic environment. A number of factors affect the entire process and include: (i) temperature of the substrate, (ii) loading rate, (iii) concentration of solids, (iv) reaction time, (v) pH, (vi) concentration of nutrients, and (vii) the presence of any toxic substances.

In terms of temperature, the optimal temperature (where digestion and gasification proceeds at the highest rate) is 35°C (95°F). Below 15°C (59°F), the rate is so slow that very little gas is produced. Temperature is also dependent on the bacterial populations: mesophilic or thermophilic. Mesophilic bacteria prefer temperatures ranging from 30 to 40°C (86 to 104°F). Thermophilic bacteria prefer temperatures ranging from 50 to 60°C (122 to 140°F). The loading rate is the amount of fermentable matter that is fed into the digester per cubic meter of digester capacity. Any change in loading rate affects the balance inside the digester, so it should be kept constant. For a given capacity, if the loading rate is increased, the fermentation period is correspondingly increased. The common range of solid concentration is 7 to 9% w/w. Digression from this range can cause fermentation to be retarded. The reaction time is the amount of time the fermentable material resides inside the digester. It has been observed that maximum gas production takes place within the first four weeks, and then gradually tapers off. Detention time can be significantly reduced if the temperature is raised or the contents of the digester are agitated, or the supply of nutrients in the digester is augmented.

Optimal gas formation occurs at pH of 7 to 8. If the pH becomes too acidic, gas production could stop altogether. Bacteria use nitrogen, phosphorus, and potassium for their nutrients. Once these are available, fermentation proceeds very quickly. Usually, some type of nutrient source is needed to help stimulate gas production. Toxic substances such as copper and its derivatives can inhibit gas production if found in large quantities. This is rare, however.

Essentially all organic material can be digested except for the stable woody materials since the anaerobic microorganisms are unable to degrade lignin. The biogas which is formed has a high CV and is considered as a renewable energy source. The main disadvantages of this process are (i) the possible presence of volatile siloxanes in the biogas that can cause serious damage in the energy users engine and boiler due to the formation of microcrystalline silica; and (ii) the increased concentration of heavy metals and various industrial “organics” in the residual sludge due to the significant reduction of the organic fraction during digestion, leaving the mineral and non-degradable fraction untouched.

Biogas can be used for electricity generation, combined heat and power (CHP), cogeneration, vehicle fuels (CNG), and production of liquid fuels. The liquid fuels would be low sulfur, low ash fuels that can be made for commercial use and easier to store, handle, and transport. Biogas can also be upgraded to pipeline quality for introduction into natural gas transmission lines and distribution to customers.

Waste Disposal – Briquetting

Historically, briquettes (especially coal and coke briquettes) have been used for fuel for approximately one hundred years. However, with the advent of modern fuel systems, the use of briquettes use has declined and the use for these products is found most often in the operation of barbecue units. While still a marketable product for such use, briquettes as fuel (such as *smokeless fuel*) are not used often for domestic and industrial heating. Briquette manufacture (*briquetting*) involves the collection of combustible materials that are not usable as such because of their low density and compressing them into a solid fuel product of any convenient shape that can be burned. Using waste materials as a means to produce briquettes is investigated in this section.

Briquettes from waste materials are commonly made from a combustible material and binder. Combustible materials include char, low-grade biomass, and bagasse. Low-grade biomass includes grasses, weeds, thinning branches, forest waste resulting from logging, agricultural waste, sawdust, wood shavings, and leaves. A binding agent is usually necessary to increase the cohesion of the combustible materials. If the combustible material is not well-bound, the briquette will crumble when removed from the mold. The binding agents can include animal manure, treated and dewatered sewage sludge, starch, wax, clay, molasses, cement, wood pitch glue, and local plant resin or synthetic resin. A binder must not cause smoke or gummy deposits, and the creation of excess dust must also be avoided. For this reason, the use of non-combustible binding agents such as clay, cement, and other adhesive minerals are kept to a minimum. Typically, starch is used because it is relatively cheap and easily available. Since bagasse briquetting is often done on site or close to a sugar factory, molasses is usually the binding agent used for bagasse briquettes.

Briquette manufacture has six basic steps: drying of carbonaceous material, size reduction, mixing, briquetting, drying of briquettes, and packaging (Figure 10.5). For the manufacture of briquettes from bagasse, an additional step is necessary, and the order is a bit different: size reduction, drying of carbonaceous material, carbonization, mixing, briquetting, drying of briquettes, and packaging. The combustible material needs to be sufficiently dried so that it will burn evenly. Low-grade biomass needs to be sundried for 5 to 7 days. Usually, moisture is removed from bagasse by open air drying or by using forced, heated air in a large rotating drum.

The size of the material often needs to be reduced to a uniform size. This assists in uniform combining, briquetting, and burning. Char is finely crushed and passed through various screens to ensure small particle sizes. Bagasse is usually chopped, rolled, or hammered to produce small pieces.

In the carbonization step, bagasse is combusted in a limited supply of oxygen in a buried pit or trench until it carbonizes into charcoal. In the briquetting step, the mixture is tightly compacted through a manually operated or automatic press or extruder. The press or extruder for briquetting must be well-designed, strongly built, and capable of agglomerating the mixture sufficiently for it to be handled through the drying process. The extruder forms rolls of charcoal, while chunks of charcoal are produced using the press. On the other hand, sawdust briquettes are formed under sufficiently high pressure to produce cohesion between wood particles. Briquettes often need to be further dried after the briquetting step. Briquettes are dried in the sunlight approximately three days before use. Rolls of charcoal formed from extruders will break into chunks during the drying process.

Historically, briquettes and fuel wood were used until the development of crude oil-based energy. However, many developing countries were left behind in the energy revolution and continued to use plain char, home-made briquettes, or fuel wood. The combination of an exploding population and high rates of deforestation in developing countries have led to severe shortages of fuel wood. Because of improved processing and by using waste to produce briquettes, briquettes can be an economical option for fueling household energy needs in developing countries. Waste-derived briquettes burn and produce very little ash (<5% w/w) with little to no odor.

See also: Briquette, Briquette Manufacture.

Waste Disposal – Enzymatic Hydrolysis

Enzymatic hydrolysis was developed to better utilize both cellulose and hemicellulose from lignocellulosic materials. The enzymatic process must be preceded by extensive pre-treatment to separate cellulose, hemicellulose, and lignin. Because milder conditions are used compared to acid hydrolysis of cellulose, subsequent enzymatic hydrolysis of the

cellulose does not degrade pentoses during pre-hydrolysis. Cellulose is a homopolysaccharide of glucose linked by 1,4-glycosidic bonds. Enzymatic hydrolysis of cellulose proceeds in several steps to break glycoside-type bonds by the action of a system of enzymes known as cellulase. The system of enzymes also contains hemicellulase to hydrolyze any hemicellulose not solubilized by prehydrolysis. Unfortunately, enzymatic technologies are not likely to be suitable for unsorted municipal solid waste due to its high heterogeneity, and further research is necessary to convert wastes that are very high in hemicellulose.

In a fermentation process, glucose is fermented to produce a dilute ethanol-water solution (dilute beer). Xylose is difficult to convert to ethanol, but it does occur. Lignin, which is not susceptible to biological transformation, can be chemically upgraded or, more frequently, simply burned as boiler fuel.

Simultaneous saccharification and fermentation (SSF) has been developed for fermenting sugars released from lignocellulose. The process combines hydrolysis and fermentation to overcome end product inhibition. By combining hydrolysis and fermentation, glucose is rapidly removed before it can inhibit further hydrolysis. In the process, biomass feedstock is milled and then pre-hydrolyzed to yield a mixture of pentoses (xylose and arabinose) and fiber. The mixture is neutralized with limestone and mixed with cellulose and hemicellulose enzymes. The cellulose and any remaining hemicellulose are solubilized to hexose (glucose) and pentoses (xylose and arabinose), which are immediately fermented to ethanol. The optimum temperature for the hydrolysis/fermentation reaction is between the optimum temperature for cellulase activity and the best temperature for the yeast. Lignin is separated from the mixture and used as boiler fuel or converted to high-value octane enhancers that can be used as blend components to produce gasoline.

Distillation is a process such as when beer is distilled to ethanol. Energy consumption in the distillation process is partly responsible for criticism that ethanol production consumes more energy than it produces. Though there is basis for criticism in older plants, modern plants pay close attention to energy consumption. The ethanol produced is commercial-grade ethanol with all of the same expected properties and can be produced from a variety of waste materials.

There are several environmental considerations when using the acid hydrolysis process. In the process, water use is very high and, furthermore, when large amounts of acid are used, not only is corrosion and leakage of acid a problem, neutralization steps and chemicals are also needed. The process to collect, transport, and process wastes into ethanol is difficult. For best results, cellulose, hemicellulose, and lignin should be processed separately.

Waste Disposal – Gasification

Gasification is a process that converts carbonaceous fuel into a combustible gas known as synthesis gas (CO and H₂) by partial combustion (oxygen-starved environment); the gas is nearly tar-free. Gasification is regarded as a key thermochemical conversion technology and offers the flexibility to be integrated into several industrial processes as well as power generating systems. Gasification compared to incineration has the added benefit that all of the organic material is fully converted to fuel for electricity generation or chemical production. Gasification systems have been reported to be more efficient for electricity generation when compared to incineration.

Gasification followed by synthesis to liquid fuels was first applied to coal in Germany during the 1920s, using technology developed by German researchers Franz Fischer and Hans Tropsch (the technology is now known as the Fischer-Tropsch process). During World War II, Germany, as well as Japan, produced diesel from coal, and South Africa later used coal-to-liquid (CTL) technology in response to international embargoes on crude oil. In principle, numerous process configurations exist for gasification products to fuels, depending upon the feedstock, gasifier type, the gas cleaning process, the product fuel, and whether electricity is cogenerated using part of the syngas output from the gasifier.

Agricultural, industrial, and urban waste has considerable promise as a feedstock for gasification because it contains relatively more lignin, which biological processes cannot convert. Unusable or low-value wastes such as furniture-making wood waste, beechwood, nutshells, olive husks, grape residues, bajra stalks, sweet sorghum stalks, bagasse, sugarcane leaves, sawdust, wood chips, corn cobs, nut shells, and rice hulls can be used as feedstock to produce high calorific value gas. Such waste is abundant in most developing countries and can be harnessed for

production of fuels and petrochemical intermediates. Knowing the potential of the waste for gasification and subsequent fuel production is essential for reducing pressure on traditional energy sources.

Gasification technology permits the production of syngas for fuel and chemical manufacture, and its application is mainly limited by gas quality (cleanliness). The research focus has been on reactor design, optimization of operating parameters, and addition of catalytically active materials to improve gas quality. Downstream clean-up of hot gas and catalytic tar conversion measures have been incorporated in modern technological designs. Gasification processes can be classified by (i) the Btu content of the product gas which can be high, medium, or low, (ii) the type of reactor hardware configuration such as single-stage design, multi-stage design, and molten salt batch reactor, as well as (iii) if the reactor is pressurized or not.

The heating value of the product gas is a function of the chemical composition, volatile constituents, and moisture content of the waste feedstock, and is carefully controlled given the application for the gas. Low Btu gas comprises a mixture of CO, H₂, and some other gases with a heating value in the range 11.15 MJ/m³ and limits its applicability to mainly chemical synthesis. Medium Btu gas consists of a mixture of methane (CH₄), carbon monoxide (CO), hydrogen (H₂), and various other gases with a heating value in the range 11.15 to 26.02 MJ/m³ and is primarily used in the synthesis of methanol, higher-molecular-weight hydrocarbon derivatives by way of the Fischer-Tropsch synthesis, and a variety of other chemicals. It can also be used as a fuel to generate steam or drive a gas turbine. The H₂-to-CO ratio in medium-Btu gas varies from 2:3 (CO-rich) to more than 3:1 (H₂-rich). The increased heating value is attributed to higher concentrations of methane and hydrogen as well as lower concentrations of carbon dioxide and the absence of nitrogen. High Btu gas consists predominantly of methane (>95% v/v) – it is compatible with natural gas and can be used as a synthetic or substitute natural gas NG (SNG).

In *single-stage* gasifiers, conversion takes place in a single reactor using steam, air, or oxygen. The common *single-stage technologies* are fixed bed, fluidized bed and entrained flow reactors. In fixed bed gasifiers, the fuel is fed from the top and the gasification medium is injected at the bottom. The fuel moves slowly down the reactor with the gas moving upwards in a countercurrent direction, whereas in co-current designs, the fuel and the gasification agent move in the same direction and the fuel must pass successively through the drying, pyrolysis, oxidation, and reduction zones. The advantage of countercurrent designs are fewer restrictions on fuel moisture and particle size, no special fuel preparation required, and a wide range of fuels can be used. By comparison, co-current gasifiers produce a better-quality gas but place strict requirements on fuel properties. Fluid bed gasifiers allow for more efficient gasification due to elimination of hot spots in the reactor. They are suitable for a wide range of feedstocks and can be scaled up to relatively large plants. They are more expensive to build and need better gas cleaning due to high particulate content in the product gas. Fluidized beds have no defined reaction zones, and the conversion of fuel and secondary pyrolytic reactions take place in the same volume. Tar conversion can be supported by introducing catalytically active bed materials.

The bed temperature is determined by the ash softening point and is usually in the range 815 to 1,040°C (1,500 to 1,905°F). Entrained flow gasifiers require pulverized fuels, and the fuels are introduced with the steam/oxygen feed and converted to gaseous products in a few seconds. Such gasifiers can be operated at lower temperatures (maintain ash as a dry solid) or at temperatures above the ash fusion temperature in a slagging mode (ash removed as a liquid). At higher temperatures, it is possible to produce a product gas which is virtually free from oil and tar. Although entrained flow gasifiers appear attractive for production of tar-free synthesis gas for petrochemical applications, challenges arise in achieving satisfactory size reduction (milling and grinding) of the waste. Single-stage gasifiers can be used for biomass and waste gasification if the requirements placed on product gas quality are low: direct co-combustion of hot raw gas or used as a fuel gas.

Various *multi-stage* processes are under development or in operation; they take into account the fuel conversion steps of drying, devolatilization, gasification, and combustion zones to enhance process efficiency and product gas quality by influencing and optimizing the operating parameters. These concepts are categorized as (i) single line, in which one mainstream of mass which pass through reactors arranged in series or (ii) double line, in which the mass mainstream is divided into at least two partial streams which pass through parallel arranged reactors. In the 'single line' process, fuel is dried and pyrolyzed in the first stage in an indirectly heated pyrolyzing unit.

The pyrolysis products undergo partial oxidation in the narrow zone between the pyrolyzer and the char gasifier. The product gas passes over the hot char bed and undergoes substantial tar cracking resulting in a higher-quality product gas. In the 'double line' process, combustion and gasification reactors are separate and are only connected by

heat transfer; a pyrolysis stage is used to split the fuel into char and gas. To provide the heat necessary for operation, the char or part of the pyrolysis gas must be oxidized outside the pyrolysis reactor.

When applied to biomass, a key advantage of gasification is that it can convert all of the organic matter into gases and then liquids, in particular lignin (component of lignocellulose resistant to enzyme attack) which is readily converted to gaseous products and made available as a fuel feedstock. Gasification of biomass from crop waste using a fluidized bed gasifier (565 to 750°C, 1,040 to 1,380°F) and an initial propane fuel source yields particulate, char, non-condensable gas, tar oil fraction, and an aqueous waste; a cyclone and a scrubber are used to condition the fuel gas.

Synthesis gas can be burnt to produce process heat and steam or used in gas turbines to produce electricity. Syngas can also be converted to a variety of fuels like hydrogen, methanol, or dimethyl ether (DME), as well as synthetic diesel and gasoline (via the Fischer-Tropsch process). Gasification followed by the Fischer-Tropsch synthesis has the potential to produce more fuel per ton of biomass.

Since the combustion of biomass imitates the natural process, the energy obtained does not add carbon dioxide to the environment. Incomplete combustion of biomass may produce organic particulate matter, carbon monoxide, and other organic acids. If high temperature combustion is used, nitrogen oxides can also be produced. The use of waste for such purposes also reduces the impact of methane emitted into the environment when organic waste decomposes in landfills. Some crop residues from conventional food crop harvests need to be left in the field to provide protection from erosion and to provide benefits such as micronutrient supplies, soil organic matter, and enhanced soil 'tilth' (the texture, structure, and pore spacing in soil).¹⁶ In cases where land is relatively flat and/or where conservation tillage methods are employed, a portion of the crop residues may be harvested for gasification. Establishment and communication of research-based guidelines are necessary to ensure that the removal of residue biomass for energy production is done in a sustainable manner.

The synthesis gas produced may contain tar, particulates, alkali compounds, and halogens that can clog filters, poison catalysts used in downstream fuel processing, or corrode the gas turbine used in electricity production. The availability of commercial quantities of waste feedstocks is another concern. Many residues have useful applications as fodder, fertilizer, and soil conditioner or as the raw material for a variety of products (particle board, medium-density fiber board (MDF), and recycled paper). In addition, availability is impacted by weather conditions (causing high and low production years in agriculture). Apart from availability, the market prices of biomass residues and waste generally depend upon a number of factors including (i) harvesting, (ii) collection and transport, (iii) market demand, (iv) local and international markets for various raw materials, and (v) the type of waste treatment technology deployed for the remaining material. The latter is particularly relevant when fees are charged to dispose of the waste, giving some organic waste streams a (theoretical) negative value.

See also: Gasification.

Waste Disposal – Incineration

Incineration is a controlled combustion process used for reducing solid wastes to carbon dioxide, water, flue gases, and ash. The ash residue may require disposal at a mono-fill or sanitary landfill given its toxicity, leaching potential, and contaminants. In addition, atmospheric emissions must be controlled to maintain good air quality. Not all solid waste can be incinerated; wastes such as white goods, industrial process waste, street and drain cleanings, and scrap steel cannot be fed to an incinerator and require alternative disposal methods. One of the most difficult aspects of waste as feedstock, whether for incineration or gasification, is its heterogeneous nature. Waste composition is influenced by numerous local conditions, such as population structure and local waste separation and recycling regulations. In addition, the composition of local waste is subject to major seasonal or even daily variations. The variability in chemical composition, water and ash content, heating value, and the presence of a number of substances, such as sulfur, chlorides, or metals, affect the performance of thermal conversion processes.

The basic technology for incineration plants was developed in Europe during the 1960s and 1970s. A major benefit of incineration is volume reduction of the original waste by 95 to 96%, thereby extending the life of landfill sites. Incineration is also used for the treatment of certain institutional wastes in niche areas as clinical wastes and certain hazardous wastes where pathogens and toxins can be destroyed by high temperatures.

Modern incineration plants reflect significant advances in addressing the technical and practical difficulties of material handling, combustion control, flue gas clean-up, and conformance with increasingly stringent air pollution control regulations. Energy recovery and production offer a direct economic benefit and lessen demands on processing and disposal requirements.

Incineration plants are usually classified as mass burn systems or refuse-derived fuel (RDF) systems and, together, account for 86 of the 98 currently operating waste-to-energy (WTE) facilities. Most mass burn systems burn waste in a single combustion chamber with excess air. The waste is burned on a sloping moving grate which helps agitate the municipal solid waste and mixes it with combustion air; many different proprietary grate systems exist. Grate design is critical because it must agitate the waste sufficiently to provide complete combustion and minimize ash carry-over in the flue gas which contributes to emissions. In the boiler/furnace portion of the incinerator, the waste characteristics of interest are the calorific value, moisture content, proportion of non-combustibles, and other components such as heavy metals, chlorine, and sulfur whose presence during combustion will result in the need for flue gas clean-up. The capacity of the furnace of the incinerator is approximately proportional to the calorific value of the waste. Mass burn produces by-products which have damaging consequences on the environment. Pollution control systems can be used to mitigate such risks. The technologies used to recover energy from municipal solid waste include (i) water-wall incineration and (ii) modular incineration.

Waterwall incineration involves the combustion of unprocessed municipal solid waste (mass burning) or processed municipal solid waste (refuse-derived fuel, RDF) in a furnace with integral boiler tubes. The advantages of water wall incineration are (i) pre-processing of waste is not required, except for large bulky items; (ii) the ash produced could be used for block manufacture, and (iii) auxiliary fuel is not required during normal steady-state operation. On the other hand, the challenges of water wall incineration are (i) complexity of operation, control and maintenance, and (ii) reserve furnace capacity is not available during downtime.

Modular incineration is used in smaller plants and is an assembly of prefabricated major components assembled in the field to form a total operation. Modular systems are similar to mass burn systems in that they combust unprocessed municipal solid waste, but they feature two combustion chambers and the municipal solid waste is charged into the system by a hydraulic ram and combustion takes place on a series of stationary hearths. Municipal solid waste is pushed from one hearth to the next by hydraulic rams. Two types of modular systems have been built and operated: starved air (slightly oxygen-deficient) and excess air (greater than stoichiometric). The advantages of modular incineration are the relatively low cost and shorter field construction time given their modular construction. The disadvantages of modular incineration are waste burnout is not always complete (increased ash quantities and reduced energy recovery); combustion control is less effective (possibility of discharge of trace organics); lower quality of equipment; and less redundancy than larger mass-fired water wall and refuse-derived fuel waste-to-energy (WTE) plants.

Feedstock preparation plays an important role in any thermal waste conversion approach. *Refuse-derived fuel* (RDF) is made when municipal solid waste is processed by mechanical means [picking, separation of inert materials (glass, minerals, ferrous and non-ferrous metals), flailing, screening, shredding, and conditioning] to produce a more homogenous material prior to incineration. Refuse-derived fuel systems utilize *pre-treated* municipal solid waste. Several types of refuse-derived fuel are made – coarse, fluff, powder, densified. They differ in complexity, power requirements, particle size, and whether the material is compacted into pellets or briquettes. Refuse-derived fuel can be used as the primary fuel source in a dedicated boiler or co-fired with a conventional fossil fuel as natural gas (NG) or landfill gas (LFG). The heating value of nearly all solid waste fuels is a function of carbon content. Ash content is generally low, but the amount of moisture is highly variable and depends upon moisture generation plus the effects of processing, handling, and storage.

Scrap tires can be processed into a waste-derived fuel (WDF) and mixed with other fuels without major alteration to the existing combustion facility. Tire-derived fuels (TDFs) are commonly used as supplemental fuel in cement kilns which are technologically and environmentally superior for selective waste disposal due to favorable internal kiln conditions as flame temperature (1,850°C, 3,360°F), residence time, alkaline environment, high gas turbulence, and mixing which ensure complete combustion, and the added benefit of having no bottom ash disposal problem since the residual materials (*e.g.*, steel from steel belted s) are incorporated into the clinker. The rationale behind the use of tire-derived fuel is as follows: (i) excellent combustion characteristics and high heating value, HHV, (ii) good availability, (iii) relatively low sulfur content, especially on a Btu basis, and (iv) reducing the environmental burden and health effects of tire stockpiles.

The full potential of incineration is not being realized because of widespread fears regarding environmental pollution. Modern incineration plants with adequate environmental safeguards and careful monitoring have been shown to be safe, and it is a technology that is likely to increase in importance during the next several decades. As environmental regulations continue to get stricter and the space for landfilling dwindles, production of refuse-derived fuels/waste derived fuels (RDF/WDF) holds promise from an energy content perspective (municipal solid waste is a renewable, abundant cheap resource) and because its conversion to energy alleviates disposal problems. The most publicized concerns related to the incineration of municipal solid waste involve the fear that it produces significant amounts of dioxin and furan emissions. Dioxin derivatives and furan derivatives are considered by many to be serious health hazards; thus, incineration for waste disposal and energy production remains a controversial topic for waste management.

Waste Disposal – Pyrolysis

Pyrolysis is a thermochemical decomposition process involving the controlled burning or heating of a material carried out in the absence of oxygen, the product being synthesis gas, liquid, and char. In addition to liquid fuel or oil, pyrolysis generates a medium-BTU gas that after purification can be used as a fuel gas. Pyrolysis aims to convert waste into other valuable chemicals, which can be used as feedstock for downstream industrial processes or transportation fuels. In fact, all of the pyrolysis products have the potential of being fuels or intermediaries for producing other valuable products for the petrochemical industry.

Depending upon the operating conditions (temperature, heating rate, particle size, and solid residence time); pyrolysis can be divided into three subclasses: conventional, thermal or catalytic, fast or flash. For example, to maximize bio-oil production, fast/flash pyrolysis is used, heating the biomass to approximately 500°C (930°F) for less than ten seconds. In plastics pyrolysis, the macromolecular structures are broken down into smaller molecules (oligomers and monomers); further degradation depends on temperature, residence time, presence of catalysts, and other process conditions.

Molten salts such as lithium chloride-potassium chloride with 10% w/w cuprous chloride (LiCl-KCl-10% CuCl) at 520°C (970°F) are used to pyrolyze polymeric waste to yield a fuel oil. At a process temperature of 420°C (790°F), the gaseous fraction is minimized; this enables a higher liquid and solid fraction to be recovered. The recovered fractions consist of low-boiling oils, aromatics, paraffin waxes, and monomers.

Catalytic cracking involves a suitable catalyst to carry out the cracking reaction. The presence of catalyst lowers the reaction temperature and time. Catalytic degradation yields a narrow product distribution with a peak at lower boiling hydrocarbon derivatives and occurs at lower temperatures. Using solid acid catalysts, HZSM-5, HY, rare earth metal-exchanged Y-type (REY) zeolite, and silica-alumina for polymeric waste yield 30% v/v naphtha and 20% v/v high-boiling oil. The differences among catalysts arise in the production of coke and gas fractions. Formation of coke is not desirable as it results in catalytic deactivation by fouling and plugging the pore paths. Catalytic cracking, owing to its lower operating temperature, appears to be more technologically sound than thermal pyrolysis. The addition of a catalyst enhances the conversion and fuel quality, as compared to pure thermal pyrolysis.

There are numerous proposed mechanisms for catalytic degradation. These include the carbonium ion mechanism and the free radical mechanism. In the carbonium ion (R^+) mechanism, there are four steps: (i) initiation, (ii) depropagation, (iii) isomerization, and (iv) aromatization. In the initiation step, the carbonium ion is generated through proton addition to an olefinic linkage, beta-scission, or through random hydride ion abstraction by low-molecular-weight carbonium ions:

In the depropagation step, the molecular weight of the main polymer chain can be successively reduced through beta-scission. In the isomerization step, the carbonium ion intermediates can undergo hydrogen atom shift or carbon atom shift, leading to rearrangement of the molecules. Some of the carbonium ion intermediates can also undergo cyclization reactions, which leads to the formation of aromatics (aromatization step).

In the free radical mechanism, there are the three known radical mechanism steps: initiation, propagation, and termination. Normally, random bond breaking generates a radical (initiation). Then, the radical is propagated via a number of reactions such as beta-scission, radical abstraction, and radical decomposition (propagation step). Finally, recombination of two radicals leads to the termination step:

Initiation:

Propagation:

Termination:

Catalytic degradation of plastics is believed to have the greatest potential to be developed into a commercialized process. The oil produced in this process resembles the regular gasoline in all respects and reportedly gives better mileage as compared to commercial gasoline.

Thermal cracking (pyrolysis) involves the degradation of polymeric materials by heating in the absence of oxygen and is usually conducted between 350 to 900°C (660 to 1,650°F). The products formed are a carbonized char and a volatile fraction that may be separated into condensable hydrocarbon oil consisting of paraffins, iso-paraffins, olefins, naphthenes, aromatics, and a non-condensable high calorific value gas. The thermal pyrolysis of polymeric waste at temperatures higher than 480°C (895°F) yields a gas-liquid hydrocarbon. At 650 to 760°C (1,200 to 1,400°F), more of the gaseous product is generated; conversely, at lower temperatures, up to 85% of the product is a liquid hydrocarbon.

The portion of each fraction and their precise composition depends primarily on the nature of the plastic waste and process conditions. Both the gaseous and liquid form of the polymeric waste can be utilized as a feed stream to petrochemical facilities. Generally, thermal cracking results in liquids with low octane value and high residue content at moderate temperatures; this is an inefficient process for producing gasoline ranges. The gaseous products obtained by thermal pyrolysis are not suitable for use as fuel products and require further refining to be upgraded to usable fuel products. A few researchers have sought to improve the thermal pyrolysis of waste plastics without employing the use of a catalyst.

Typically, discarded tires can be reduced in size by grinding, chipping, and pelletizing and passed through a classifier to remove the steel belting after which the chips are pyrolyzed for 1 hr at a temperature of 300 to 500°C (570 to 930°F) and then heated for 2 hours in a closed retort. The products are then distilled (purification and analysis); this yields oil and gas and char. However, discarded tires can also be shredded to 25 mm and ground to 24 mesh as a feed preparation step for occidental flash pyrolysis which involves flash pyrolysis and product collection. The pyrolytic reaction occurs without the introduction of hydrogen or using a catalyst. This yields a gaseous stream that is passed to a quench tower from which fuel oil and gas (recycled to char fluidized and pyrolysis reactor as a supplemental fuel) and carbon black (35% w/w) is produced.

Hydrothermal liquefaction and pyrolysis are often confused since both are thermochemical processes where organic compounds are converted to liquid products. However, in hydrothermal liquefaction, macro-molecules are

decomposed into unstable, reactive low-boiling molecules in the presence of a catalyst. These fragments repolymerize into high-molecular-weight oily compounds. The process involves solvolysis, decarboxylation, hydrogenolysis, and hydrogenation, leading to challenging mechanistic transformation studies. During solvolysis, the solvent reacts with the molecule, helping to begin the degradation of the biomass. Depolymerization of hemicelluloses, cellulose, and lignin further degrades the biomass to smaller molecules. In decarboxylation, loss of carbon dioxide can lead to rearrangement of the molecule. Molecules can also be further transformed via hydrogenolysis (water molecules split into H^+ and OH^- and react with molecules) and hydrogenation (H_2 is added to the molecule).

In proteinaceous wastes, proteins degrade to amino acids which can degrade into low-molecular-weight carboxylic acids. In cellulosic wastes, cellulose degrades into glucose by hydrolysis, which degrades into a number of aldehydes and ketones. These aldehydes and ketones can then be degraded to low-molecular-weight carboxylic acids also. Finally, plastic wastes such as PET, polypropylene, and polyethylene degrade into TPA, ethylene, and glycol. These degradation products can be further degraded to low-molecular-weight carboxylic acids also. The low-molecular-weight carboxylic acids can be converted to volatile carbon (carbon dioxide, carbon monoxide) and water.

The cellulose-based constituents of municipal solid waste are segregated and undergo a pyrolytic reaction at 116°C (240°F) and atmospheric pressure, yielding a liquid fuel ($\text{C}_6\text{H}_8\text{O}$, dependent on feedstock composition and reaction temperature).

For a pyrolytic reaction temperature of 500 to 900°C (930 to $1,650^\circ\text{F}$) and a pressure of 1 atmosphere, the products are solid, liquid, and gaseous fuels such as low-boiling oil (benzene), liquor (dissolved organics in water), and gas (town gas, manufactured gas, hydrogen, carbon monoxide, methane, volatile hydrocarbon derivatives). Municipal solid waste mixed with polyethylene chips and pyrolyzed at 100 to 400°C (212 to 750°F) at atmospheric pressure yielded similar products with lesser amounts of gas.

Pyrolysis products are used for electricity generation, heating, fuels (gaseous, liquid, solid), and feedstock to refineries for upgrade and petrochemical manufacture. Pyrolysis oils can be used in many applications, such as combustion in boilers, stationary diesel engines, industrial combustion turbines, and Stirling engines. The comparative option of upgrading these oils for vehicle engines does not appear promising. Conversion of industrial, urban, farm, agricultural, crop, and forestry waste to clean, sustainable energy is one of the major benefits of pyrolysis.

Several challenges must be overcome before pyrolysis can become a commercially viable means for energy production. Pyrolysis oils require downstream processing as they may contain char, alkali metals, 20 to 25% v/v water, as well as acid derivatives that are temperature sensitive and highly viscous which results in storage and engine problems.

Waste Management

The fuels production industry – including the non-renewable energy industry and the renewable energy industry – will increasingly feel the effects of the land bans on the hazardous waste management practices. Current practices of land disposal must change along with management attitudes for waste handling. The way refineries handle their waste in the future depends largely on the ever-changing regulations. Waste management is the focus, and reuse/recycle options must be explored to maintain a balanced waste management program. This requires that a waste be recognized as either *non-hazardous* or *hazardous*.

However, before a refinery can determine if its waste is hazardous, it must first determine that the waste is indeed a solid waste. In 40 CFR 261.2, the definition of solid waste can be found. If a waste material is considered a solid waste, it may be a hazardous waste in accordance with 40 CFR 261.3. There are two ways to determine whether a waste is hazardous. These are to see if the waste is listed in the regulations or to test the waste to see if it exhibits one of the characteristics (40 CFR 261).

There are four lists of hazardous wastes in the regulations. These are wastes from nonspecific sources (F list), wastes from specific sources (K list), acutely toxic wastes (P list), and toxic wastes (U list). And there are the four characteristics mentioned before: ignitability, corrosivity, reactivity, and extraction procedure toxicity. Certain waste

materials are excluded from regulation under RCRA. The various definitions and situations that allow waste to be exempted can be confusing and difficult to interpret. One such case is the interpretation of the *mixture* and *derived-from* rules. According to the mixture rule, mixtures of solid waste and listed hazardous wastes are, by definition, considered hazardous. Likewise, the *derived-from* rule defines solid waste resulting from the management of hazardous waste to be hazardous (40 CFR 261.3a and 40 CFR 261.1c).

There are five specific listed hazardous wastes (K list) generated in refineries. These are K048-K052. Additional listed wastes, those from nonspecific sources (F list) and those from the commercial chemical product lists (P and U lists), may also be generated at refineries. Because of the mixture and derived-from rules, special care must be taken to ensure that hazardous wastes do not *contaminate* non-hazardous waste. Under the mixture rule, adding one drop of hazardous waste in a container of non-hazardous materials makes the entire container contents a hazardous waste.

As an example of the problems such mixing can cause, consider the case with API separator sludge that is a listed hazardous waste (K051). The wastewater from a properly operating API separator is not hazardous unless it exhibits one of the characteristics of a hazardous waste. That is, the derived-from rule does not apply to the wastewater. However, if the API separator is not functioning properly, solids carry-over in the wastewater can occur. In this case, the wastewater contains a listed hazardous waste, the solids from the API sludge, and the wastewater would be considered a hazardous waste because it is a mixture of a non-hazardous waste and a hazardous waste.

This wastewater is often further cleaned by other treatment systems (filters, impoundments, etc.). The solids separating in these systems continue to be API separator sludge, a listed hazardous waste. Therefore, all downstream wastewater treatment systems are receiving and treating a hazardous waste and are considered hazardous waste management units subject to regulation. Oily wastewater is often treated or stored in unlined wastewater treatment ponds in refineries. These wastes appear to be similar to API separator waste.

Waste Management – Biological Methods

The purpose of a biological treatment system is to control the environment for microorganisms so that their growth and activity are enhanced, and to provide a means for maintaining high concentrations of the microorganisms in contact with the wastes. Thus, biodegradation is the use of living organisms (primarily microorganisms) to degrade pollutants previously introduced into the environment or to prevent pollution through treatment of waste streams before they enter the environment. Biological waste treatment is a generic term applied to processes that use microorganisms to decompose organic wastes either into water, carbon dioxide, and simple inorganic substances, or into simpler organic substances, such as aldehydes and acids. In the context of this book, biodegradation is the process of treating waste by biological methods while biodegradation is the outcome of the bioremediation process.

Biodegradation is emerging as one of several alternate technologies for removing pollutants from the environment, restoring contaminated sites, and preventing further pollution. On the other hand, biodegradation of waste is the conversion of waste chemicals by biological processes to simple inorganic molecules and, to a certain extent, to biological chemicals. The complete bioconversion of a substance to inorganic species such as carbon dioxide, ammonia, and phosphate (often referred to as mineralization).

Since biological treatment systems do not alter or destroy inorganic substances, and high concentrations of such chemicals can severely inhibit decomposition activity, chemical or physical treatment may be required to extract inorganic chemicals from a waste stream prior to biological treatment.

Detoxification refers to the biological conversion of a toxic substance to a less toxic species, which may still be relatively complex, or biological conversion to an even more complex chemical. An example of detoxification is the enzymatic conversion of paraoxon (a highly toxic organophosphate insecticide) to p-nitrophenol, which has only approximately 1/200 the toxicity of the parent compound.

Biodegradation is usually carried out by the action of microorganisms, particularly bacteria. However, microorganisms such as bacteria are not the panaceas for chemical wastes. Their function can vary depending upon the specific bacterium and the metabolic processes of the bacteria.

Biotransformation is the conversion of a substance through metabolism, thereby causing an alteration to the substance by biochemical processes in an organism. Metabolism is divided into the two general categories of catabolism, which is the breaking down of more complex molecules, and anabolism, which is the building up of life

molecules from simpler chemicals. The substances subjected to biotransformation may be naturally occurring or anthropogenic (made by human activities). They may consist of xenobiotic molecules that are foreign to living systems.

An important biochemical process that occurs in the biodegradation of many chemical waste chemicals is co-metabolism. This does not serve a useful purpose to an organism in terms of providing energy or raw chemical feedstocks to produce biomass, but occurs concurrently with normal metabolic processes. An example of co-metabolism of chemical waste is provided by the white rot fungus which degrades a number of kinds of organic chlorine compounds (including polychlorobiphenyl derivatives, cyanide derivatives, and chlorodioxin derivatives) under the appropriate conditions. The enzyme system responsible for this degradation is an enzyme that the fungus uses to break down lignin in plant material under normal conditions.

Biodegradation of chemical waste that can be metabolized takes place whenever the wastes are subjected to conditions conducive to biological processes. The most common type of biodegradation is that of organic compounds in the presence of air, that is, aerobic processes. However, in the absence of air, anaerobic biodegradation may also take place. Furthermore, inorganic species are subject to both aerobic and anaerobic biological processes.

Although biological treatment of chemical waste is normally regarded as degradation to simple chemical species such as carbon dioxide, water, sulfates, and phosphates, the possibility must always be considered of forming more complex (in some cases hazardous) chemical species. An example of the latter is the production of volatile, soluble, toxic methylated forms of arsenic and mercury from inorganic species of these elements by bacteria under anaerobic conditions.

Physical-chemical and biological treatment processes are employed as for wastewater treatment. In addition, chemicals are introduced for precipitation of nutrients, followed by coagulation and filtration for removing solids remaining after biological treatment. In some cases, granular activated carbon or membrane filtration (Noble and Stern, 1995) or a combination of membrane-assisted solvent extraction is used for additional purification of the groundwater streams and waste streams. This higher level of treatment is advisable because of the damage that any visual traces of chemical waste can do to the appearance of the waters. In addition, the treatment may combat the potential eutrophic effect that the nutrients phosphorus and nitrogen can have on the receiving water.

For the most part, anthropogenic compounds resist biodegradation much more strongly than do naturally occurring compounds. This is generally due to the absence of enzymes that can cause an initial attack on the compound. A number of physical and chemical characteristics of a compound are involved in its amenability to biodegradation. Such characteristics include hydrophobicity, solubility, volatility, and affinity for lipids. Some organic structural groups impart particular resistance to biodegradation. These structural groups include branched carbon chains, ether linkages, meta-substituted benzene rings, chlorine, amines, methoxy groups, sulfonates, and nitro groups.

Actinomycetes are microorganisms that are morphologically similar to both bacteria and fungi. They are involved in the degradation of a variety of organic compounds, including degradation-resistant alkanes and lignocellulose. Other compounds attacked include pyridine derivatives, phenol derivatives, non-chlorinated aromatic derivatives, and chlorinated aromatic derivatives.

Fungi are particularly noted for their ability to attack long-chain and complex hydrocarbon derivatives and are more successful than bacteria in the initial attack on polychlorobiphenyls. Phototrophic microorganisms, which include algae, photosynthetic bacteria, and cyanobacteria (blue-green algae) tend to concentrate organophilic compounds in their lipid stores and induce photochemical degradation of the stored compounds.

Usually, the products of biodegradation are molecular forms that tend to occur in nature and that are in greater thermodynamic equilibrium with their surroundings than the starting materials. Detoxification refers to the biological conversion of a toxic chemical to a less toxic chemical species.

Microbial bacteria and fungi possess enzyme systems required for biodegradation of wastes are usually best obtained from populations of indigenous microorganisms at a chemical waste site where they have developed the ability to degrade particular kinds of molecules. Although it has some shortcomings in the degradation of complex chemical mixtures, biological treatment offers a number of significant advantages and has considerable potential for the degradation of chemical wastes, even in situ.

The biodegradability of a compound is influenced by its physical characteristics, such as solubility in water and vapor pressure, and by its chemical properties, including molecular mass, molecular structure, and presence of various kinds of functional groups, some of which provide a “biochemical handle” for the initiation of biodegradation. With the appropriate organisms and under the right conditions, even substances such as phenol that are considered to be biocidal to most microorganisms can undergo biodegradation.

Properties of chemical wastes and their media can be changed to increase biodegradability. This can be accomplished by adjustment of conditions to optimum temperature, pH (usually in the range of 6 to 9), stirring, oxygen level, and the amount of the material. Biodegradation can be aided by removal of toxic organic chemicals and inorganic chemicals, such as ions of the heavy metal.

Aerobic processes for the treatment of waste utilize aerobic bacteria and fungi that require molecular oxygen. These processes are often favored by microorganisms, in part because of the high energy yield obtained when molecular oxygen reacts with organic matter. Aerobic and anaerobic digestion processes have been adapted to the use of an activated sludge process. These treatments can be applied to wastes such as chemical process wastes and landfill leachates. Some systems use powdered activated carbon as an additive to absorb nonbiodegradable organic wastes.

Anaerobic processes for the treatment of waste are those processes in which microorganisms degrade wastes in the absence of oxygen and can be practiced on a variety of organic wastes. Compared to the aerated activated sludge process, anaerobic digestion requires less energy, yields less sludge by-product, generates hydrogen sulfide which precipitates toxic heavy metal ions, and produces methane which can be used as an energy source.

Activated sludge is the biologically active sediment produced by the repeated aeration and settling of sewage and/or organic wastes. The dissolved organic matter acts as food for the growth of aerobic flora. These species produce a biologically active sludge which is usually brown in color and which destroys the polluting organic matter in the sewage and waste. The process is known as the activated sludge process.

Briefly, the activated sludge process is a versatile and effective waste treatment process. Microorganisms in the aeration tank convert organic material in wastewater to microbial biomass and carbon dioxide. Organic nitrogen is converted to ammonium ion or nitrate, and organic phosphorus is converted to orthophosphate.

The microbial cell matter formed as part of the waste degradation processes is normally kept in the aeration tank until the microorganisms are past the log phase of growth, at which point the cells flocculate and separate from the liquid. These solids settle out in a settler, and a fraction of them is discarded. Part of the solid the return sludge, is recycled to the head of the aeration tank and comes into contact with fresh sewage. The combination of a high concentration of microorganisms in the return sludge and a rich food source in the in-flowing sewage provides optimum conditions for the rapid degradation of organic matter.

However, in terms of pollution by humans, sewage sludge is not the beneficial organic fertilizer that many believe it to be. Sewage sludge spread on land may contaminate water by release of a variety of organic and inorganic contaminants. The spread of disease in ancient and medieval times due to contamination of water supplies will attest to this (Cartwright and Biddis, 1991). Similarly, chemicals leached from landfills by (acid) rain can also cause serious contamination of land and water systems. In addition, leachates from unlined pits and lagoons containing chemical liquids/sludge may pollute cause a specific pollution (drinking water) problem or a more general pollution problem.

Soil is a natural medium for a number of living organisms that may have an effect upon biodegradation of chemical wastes. Of these, the most important are bacteria. Wastes that are amenable to land treatment are biodegradable organic substances. However, in soil contaminated with chemical wastes, bacterial cultures may develop that are effective in degrading normally recalcitrant compounds through acclimation over a long period of time. Land treatment is most used for crude oil refining wastes and is applicable to the treatment of fuels and wastes from leaking underground storage tanks.

Land treatment can also be applied to biodegradable organic chemical wastes, including some organic halogen compounds. Land treatment is not suitable for the treatment of wastes containing acids, bases, toxic inorganic compounds, salts, heavy metals, and organic compounds that are excessively soluble, volatile, or flammable.

Bioreactors have been used for wastewater treatment processes for decades. The reactors may be either fixed film or slurry phase. Fixed film reactors are similar to the traditional trickling filters or rotating biological contactors (RBCs) of the wastewater industry. In either case, the microorganisms are supported on the medium of the filter. The

wastes are passed over the filter (or in the case of rotating biological contactors, the filter is passed over the waste) allowing the microorganisms to come into contact with the wastes and break down the organic chemical. Slurry phase reactors are tanks into which the wastes, nutrients, and microorganisms are placed. The tank is mixed and may be aerated. In many instances, contaminated groundwater is used to create the waste slurry. Both fixed film and slurry phase treatments are either batch or continuous mode.

Waste Management – Chemical Methods

The effects of chemical waste on the environment are reflected by the effects on organisms and effects on the overall ecosystem. It is also worth remembering that virtually all chemical wastes are harmful to humans, even poisonous, depending upon the amount ingested. As with all environmental pollutants, such chemical wastes eventually reach a state of physical and chemical stability and equilibrium with the environment, although it may take many centuries to occur. In many cases, the behavior (or reactivity) and ultimate fate of a chemical waste is a function of its physical properties and surroundings. On the basis that it is not possible to wait for the chemical to reach an equilibrium with its surroundings, methods of remediation are essential.

The first step in considering the appropriate technology to employ to treat a specific waste is to determine whether the waste is hazardous or nonhazardous. And the definition of a hazardous/nonhazardous waste is determined by the relevant legislation. There is the general tendency to think of a chemical waste as some obscure and ill-defined sludge discarded from a process. However, chemical waste can also be in the form of volatile organic compounds (VOCs), semi-volatile organic compounds (SVOCs), metals, radioactive chemicals, radioactively contaminated materials, or a mixture of any or all of these types.

The ideal treatment process reduces the quantity of chemical waste to a small fraction of the original amount and converts it to a nonhazardous form, if such a conversion is possible. Another consideration in selecting a treatment technology is the location where the wastes are to be treated. For example, wastes may be treated in place (in situ), within the confines of the site, or at an off-site facility (ex situ).

There are various alternative waste treatment technologies, such as chemical treatment and biological treatment. Chemical treatment process and physical treatment processes as well as thermal methods of treatment (including incineration) as well as solidification or stabilization are processes that are used to (i) destroy the waste by complete elimination of the chemical or (ii) by conversion of the chemical to a benign form and produce a final residual chemical that is suitable for disposal.

The effectiveness of the application of each of these technology groups to a specific waste varies depending on (i) the type of waste, (ii) the concentration of the individual components in the waste, (iii) the physical phase of the chemical, (iv) the desired level of treatment, and (v) the final method of disposal of any remaining residue. The waste characteristics can include such properties as volatility (gases, volatile chemicals in water, gases, or volatile chemicals adsorbed on solids, such as catalysts), liquid phase chemicals (such as organic solvents), dissolved or soluble chemicals (water-soluble inorganic species, water-soluble organic species, compounds soluble in organic solvents), semisolid chemicals (sludge, grease), and solid chemicals (dry solids, including granular solids with a significant water content, such as dewatered sludge, as well as solids suspended in liquids). Waste treatment may occur at three major levels: (i) primary waste treatment, (ii) secondary waste treatment, and (iii) tertiary waste treatment, sometimes referred to as polishing.

Primary waste treatment is generally regarded as preparation for further treatment, although it can result in the removal of by-products and reduction of the quantity and hazard of the waste. Secondary waste treatment detoxifies, destroys, and removes hazardous constituents. Tertiary waste treatment (polishing) usually refers to the treatment of a waste product for safe discharge. An example is the treatment of recycled water to remove any chemicals so that it may be safely discharged or repurposed.

Typically, chemical treatment processes alter the chemical structure of the constituents of the waste to produce either an innocuous or a less hazardous by-product. Chemical processes tend to produce minimal air emissions and can often be carried out on the site of the waste generator. In fact, some chemical waste treatment processes are available as mobile units.

The applicability of chemical treatment processes to waste management depends upon the chemical properties of the waste constituents and the products of the processes. Particularly relevant properties are (i) acid-base character, (ii) oxidation and/or reduction behavior, (iii) precipitation and/or the tendency to form complexes, (iv) flammability and combustibility, (v) reactivity and corrosivity, and (vi) compatibility with other chemical waste.

Waste Management – Physical Methods

In contrast to the chemical methods of waste treatment, physical processes for the treatment of chemical waste include processes that separate components of a waste stream or change the physical form of the waste without altering the chemical structure of the constituent chemicals.

These processes – which are based upon one or more of the physical properties of the released chemical – are particularly useful for separating hazardous chemicals from an otherwise nonhazardous waste stream so that they may be treated in a more concentrated form, separating various chemical components for different treatment processes, and preparing a waste stream for ultimate destruction in a biological or thermal treatment process. These processes include (i) phase separation (filtration), (ii) phase transfer (extraction, sorption), (iii) phase transition (distillation, evaporation, precipitation), and (iv) membrane separations (reverse osmosis, hyperfiltration, and ultrafiltration).

The important aspect of physical methods of remediation is to isolate the contaminant so that it can be recovered/destroyed while being contained within a specific area. In terms of containment, there are several technologies available which usually involve construction of a containment wall (usually concrete) around the contaminated area where the side where leakage into nearby water systems can occur. One aspect of remediation that is evolving is the application of soil-mix wall technology. This technology consists of mixing soil in situ with cement grout using multiple shaft augers to construct overlapped cement columns. The use of augers makes it possible to define the treatment zone clearly and to confine the contaminant(s).

Solidification and stabilization are treatment systems which move beyond the older concept of dig-and-move and are designed (i) to improve the handling and the physical characteristic of the waste, or (ii) or to decrease the surface area across which transfer or loss of contained pollutants can occur, (iii) or to limit the solubility of, or detoxify, any chemical constituents in the waste.

Stabilization/solidification processes are being used to minimize the potential for groundwater pollution from land disposal of hazardous wastes. Many variations are used, but most rely on pozzolanic reactions to chemically stabilize and physically solidify the waste. Portland cement alone or in combination with fly ash, cement kiln dust lime, or other ingredients is the principal solidifying agent used. The processes are effective for immobilizing any heavy metals present in sludge, contaminated soils, and other wastes. They are not as effective at immobilizing toxic organic chemicals. Organically modified clays are now being evaluated as an additive to stabilization and/or solidification processes in order to adsorb and retain these organic pollutants in the solidified waste form.

The environmental acceptability of stabilization and solidification processes depends on the long-term ability of the waste form to retain contaminants. This will be governed by the chemical binding mechanisms involved and by the durability of the waste form. Widespread acceptance of stabilization and solidification processes will be hampered until the long-term durability of the waste form can be demonstrated.

Stabilization usually involves the addition of materials (chemicals or derivatives thereof) that ensure that the chemical constituents are maintained in their least soluble or least toxic form. In the solidification process, the results are obtained primarily, but not exclusively, via the production of a monolithic block of treated waste with high structural integrity. Stabilization techniques limit the solubility of, or detoxify, the waste contaminants even though the physical characteristics of the waste may not be changed. Both of these techniques might also have been classified under phase transition or phase conversion.

Encapsulation, another perhaps more specific form of waste stabilization, is a method by which mixed wastes, i.e., waste containing radioactive chemicals and higher level radioactive waste can be rendered less harmful to the environment. The use of polyethylene, chosen for its durability, has been suggested as a suitable encapsulating agent.

Waste Management – Pretreatment

Dilute and non-toxic wastewaters are normally treated in a biological treating plant prior to disposal. However, when aqueous wastes are received from a variety of sources in a large industrial organization and treated in a common biological waste treating plant, some of these waste streams may be too toxic or too reactive to be acceptable as feeds to the biological treating plant. Furthermore, different waste streams may be incompatible due to potential chemical reactions between them which could release toxic gases to the atmosphere. This is particularly true of process wastewaters from the chemical process and metal finishing industries and for chemical wastes from laboratories. Such wastes must be pretreated to remove toxic metals or other toxic ions. They must also be brought to near neutral pH (approximately 7.0) before they can be sent to either an on-site or a publicly owned water treatment works.

The incompatibility of such waste streams is usually due to one stream containing a potentially toxic-forming material such as sulfide or cyanide anions and the other containing a reactive material, like strong acids, that can release toxic hydrogen cyanide (HCN) or hydrogen sulfide (H_2S) to the atmosphere. The examples of this type of incompatibility are (i) chromium- and cyanide-containing aqueous waste streams from metal finishing, where the acid pH needed to reduce chromium from the six-valence state to the three-valence state would release toxic hydrogen cyanide (gas), and (ii) highly basic streams and streams capable of releasing toxic vapors such as ammonia in the presence of bases.

Waste Management – Thermal Methods

Outside of the traditional containment methods (land filling and capping), the application of some type of thermal process has, until recently, been the most common form of treatment for chemical waste. Thermal treatment processes have lost some popularity recently due to the threat of emissions from incomplete combustion. Except for vitrification, thermal technologies are *ex situ* processes requiring the wastes to be transported to the processing unit. However, the use of a thermal destruction technology may be (depending upon the nature of the emissions) superior to wet scrubbing technologies for emissions cleaning.

Incineration is the controlled combustion of chemicals in an enclosed area. Thus, incineration of chemical waste and, for example, sewage sludge, is a process that involves exposure of the waste chemicals to oxidizing conditions at a high temperature, usually in excess of 900°C ($1,650^{\circ}\text{F}$).

Incineration of solid and liquid chemical wastes, such as polychlorobiphenyl derivatives, is a common and highly efficient method of destruction. The destruction of polychlorobiphenyls commences at ca. 800°C ($1,470^{\circ}\text{F}$) and commercial incinerators operate at temperatures in excess of $1,000^{\circ}\text{C}$ ($1,830^{\circ}\text{F}$). Suitable for the purpose are stationary incinerators, cement kilns, incinerator ships, and smaller mobile thermal destruction units.

This, of course, is a convenient point at which to note only one of the many ways in which environmental events on land, in the air, and in the water are connected. And the connection between the air, land, and water systems is not guaranteed to be sequential:

Land systems ↔ water systems ↔ atmosphere

Briefly, emissions from the incinerators may be gaseous (SO_x , NO_x , particulate matter) which can pollute the atmosphere or, through the formation of the constituents of acid deposition, the water systems and the land systems, and therefore control is necessary.

Alternatively, these emissions might have a direct effect on the vegetation by deposition of the gases or particulate matter directly on to the land at a point downwind of the incinerator. In addition, solid waste (ash) from an incinerator can pollute the land and, as a result of leaching by rain (acidic or otherwise), pollute the water systems. Therefore, attention must be focused on the disposal of the ash.

The air emission systems from these thermal reactors, as well as from the furnaces that burn solids emanating from wastewater plants, must be designed to prevent chemical and particulate air pollution. These air emission systems include electrostatic precipitators and afterburners. In addition, sulfur-containing fuels emit sulfur dioxide

and other sulfur containing gases as a result of combustion and these sulfur-containing gases have the potential for conversion to sulfates (sulfuric acid in the atmosphere) which can be deposited on the land as sulfate.

Nitrogen oxides (also produced during fuel combustion) are converted to nitrates in the atmosphere, and the nitrates eventually are deposited on soil. Soil also adsorbs nitric oxide (NO) and nitrogen dioxide (NO₂) readily, and these gases are oxidized to nitrate in the soil. Carbon monoxide is converted to carbon dioxide and possibly to biomass by soil bacteria and fungi. Elevated levels of heavy metals (such as lead) from mines and smelters are also found on in the soil near such facilities.

Thermal treatment of chemical waste can be used to accomplish the common objectives of waste treatment which are (i) volume reduction, and (ii) removal of volatile, combustible, mobile organic matter and destruction of toxic and pathogenic chemicals. Incineration utilizes high temperatures, an oxidizing atmosphere, and often turbulent combustion conditions to destroy wastes.

The effective incineration of wastes depends upon the combustion conditions, which are (i) a sufficient supply of oxygen in the combustion zone, (ii) thorough mixing of the waste, the oxidant, and any supplemental fuel, (iii) combustion temperatures above 900°C (>1,650°F), and (iv) sufficient residence time to allow reactions to occur.

Usually, the heat required for incineration comes from the oxidation of organically bound carbon and hydrogen contained in the waste chemical or in supplemental fuel:

These reactions destroy organic matter and generate heat required for endothermic reactions, such as the breaking of C-Cl bonds in organic chlorine compounds.

Incineration detoxifies chemical waste by destroying organic compounds, reduces the volume of the waste, and converts liquid waste to a solid product by vaporizing any fluids present in the wastes. The primary use of incineration is for the destruction of volatile organic compounds and semi-volatile organic compounds. Incinerators have been extremely capable of destroying organic compounds in waste. Removal efficiencies as high as 99.9999% have routinely been achieved (often referred to as the six-9s treatment level).

Incineration systems are designed to accept specific types of chemicals which vary according to feed mechanisms, operating temperatures, equipment design, and other parameters. The main products from complete incineration include water, carbon dioxide, ash, and certain acids and oxides, depending upon the waste in question.

Waste incineration and pyrolysis processes typically include single-chamber liquid systems, rotary kilns, and fluidized-bed incineration systems. In a single-chamber liquid system, a brick-lined combustion chamber contains liquids that are burned in suspension. In addition to being the primary parts of an incineration system, these units can be used as afterburners for rotary kilns.

A rotary kiln is a versatile large refractory-lined cylinder capable of burning virtually any liquid or solid organic waste; the unit is rotated to improve turbulence in the combustion zone. Fluidized-bed incineration uses a stationary vessel within which solid and liquid wastes are injected into a heated, extremely agitated bed of inert granular material; the process promotes rapid heat exchange and can be designed to scrub off the gases.

The ideal wastes for incineration are predominantly organic chemicals that will burn with a heating value of at least 5,000 Btu/lb and preferably more than 8,000 Btu/lb. Such heating values are readily attained with waste having a high content of organic constituents. In some cases, however, it is desirable to incinerate wastes that will not burn alone and which require supplemental fuel, such as methane and crude oil liquids.

The examples of such wastes are nonflammable organic chlorine wastes, some aqueous wastes, or soil in which the elimination of a particularly troublesome contaminant is worth the expense and trouble of incinerating it. Inorganic matter, water, and organic heteroelement content of liquid waste is important in determining their susceptibility to incineration. Many wastes, including hazardous waste, are burned to produce fuel for energy recovery in furnaces and boilers. This process (co-incineration) uses combustible waste material more for energy generation than for waste destruction. In addition to heat recovery from combustible waste, an existing on-site facility, rather than a separate waste incinerator, can be used for waste disposal.

Incinerators can be designed to handle wastes in any physical state and have proven effective in treating solids, liquids, sludge, slurries, and gases. The effectiveness of an incinerator depends on three factors: (i) temperature of the combustion chamber, (ii) residence time in the chamber, and (iii) amount of mixing of the chemical with air while in the chamber.

Normal combustion temperatures range between 900 and 1,500°C (1,650 to 2,280°F); in some instances, the temperatures employed are much higher. Many incinerators for hard-to-burn compounds employ two combustion chambers. The first chamber converts the compounds to gas and initiates the combustion process. In the second chamber, combustion of the gases is completed.

There are four major components of chemical waste incineration systems: (i) preparation, (ii) combustion, (iii) pollutant removal, and (iv) ash disposal.

Waste preparation for liquid wastes may require filtration, settling to remove solid material and water, blending to obtain the most appropriate mixture for incineration, or heating to decrease viscosity. Solids may require shredding and screening. Atomization is commonly used to feed liquid wastes. Several mechanical devices, such as rams and augers, are used to introduce solids into the incinerator.

The inert portion of the waste remains as ash after incineration. For liquid waste, the amount of ash remaining is generally minimal, whereas for solid waste, the volume of ash can be as much as one-third by weight of the original material. If the ash contains metals or radioactive chemicals, it must be further treated prior to disposal. The most frequently employed method of treating the ash remaining from the incineration process is solidification/stabilization. The hot ash is often quenched in water, and, prior to disposal, it may require dewatering and chemical stabilization. A major consideration with waste incinerators and the types of wastes that are incinerated is the disposal problem posed by the ash, especially in respect to potential leaching of heavy metals.

Waste Management – Waste Exchange

Waste exchange takes advantage in an organized way of the concept that the waste held by one company may be a valuable resource for another company. In many cases, valuable materials can be recovered from waste streams, but the generator has no on-site opportunities to recycle or reuse this material. On the other hand, other divisions or units of the same company or outside companies may be purchasing this same material as a feedstock to their manufacturing operations. By selling the recovered material from the generating company to a user company at a price reflecting the savings to both companies insofar as (i) the seller does not have the expense of disposing of the material and (ii) the buyer has an economic incentive to use the recovered material rather than new material purchased in the open market.

The waste exchange concept can be an effective means for the “disposal” of laboratory chemicals that are no longer needed for the purpose for which they were originally purchased. Such chemicals may be chemicals that are unused after the completion of the project for which the chemicals were purchased and, therefore become part of a storage inventory for use at some unknown time in the future in which there are merely excess inventory.

However, if the chemicals are collected, labeled, and stored in the original containers in a convenient place accessible to potential users, they can be used by personnel other than the original purchasers in preference to making new purchases. However, this system does require a control system to provide assurance that identity and purity of the chemicals are correct and that unstable materials are not included in the chemical storage inventory.

Waste exchange between companies are usually worked out on single items which pose no threat to either company in terms of disclosure of trade secrets or proprietary process technology, or exposure to sanctions under anti-trust laws against cooperation. These factors along with the problems of negotiating equitable prices for recovered material as feeds tocks have prevented waste exchange between companies from achieving very much of its potential. The chemicals may also be offered for sale on the open market which can also apply not only to unused chemicals but also to chemicals recovered as by-products from waste streams generated in chemical manufacturing processes.

In spite of the potential obstacles to waste exchange that may arise, the concept has potential for waste minimization, and financial return should lead to increased application of this technique.

See also: Hazardous Waste, Waste.

Waste Minimization and Separation

Waste minimization has been defined as (i) source reduction, (ii) waste separation and concentration, (iii) reuse and recycling of components recovered from waste streams, and (iv) waste exchange.

Source reduction includes recycling of materials within a process, thus extending the life of the materials before disposal and as a result decreasing the amount of waste material generated. Typical operations falling into this category are (i) recycling of cutting oils in metal fabrication with chip removal by gravity or mechanical means, (ii) recycling of metal degreasing solvents with grease removal by distillation, and (3) recycling of dry cleaning solvents by distillation. Manufacturers of equipment for these operations often include the accessory equipment needed for recycling right in the process equipment package, thereby greatly extending the life of the necessary process fluids. When the sludge level in or the quality of the spent process fluids becomes too bad for "in process" recycling, the spent fluid can be removed from the process equipment and recovered for recycling in external on-site or off-site equipment. Thus, the only materials that must be finally discarded are the metal chips, sludges, and impurities recovered from the separation processes in the recycling circuits.

Waste separation and concentration describes the techniques used to recover valuable components from a waste stream in concentrations sufficiently high to make them useful as feedstocks. They could be sent back to the process from which they came or used as raw materials to other processes. In this latter case, they would be good candidates for a waste exchange where people operating different processes could trade raw materials recovered from wastes. In many cases, waste separation and concentration has a dual beneficial effect in that the removal of toxic materials from wastewater streams can make the wastewaters non-toxic and suitable for recycling or simple disposal. Thus, both the impurity and the wastewater may be recycled and removed from the hazardous waste definition.

Reuse and recycling refer to the recovery of useful material from a waste stream for reuse. This reuse can be either (i) recycling to the process it came from, assuming that the material can be recovered in sufficient purity or (ii) using the material for a less demanding purpose. For example, solvents used in the formulation of paints can be recovered by distillation and used for cleaning painting equipment. With a suitable purification process, they may even be suitable for recycling to the original use.

Waste exchange takes advantage in an organized way of the concept that one man's waste may be another man's valuable resource. In many cases, valuable materials can be recovered from waste streams, but the generator has no on-site opportunities to recycle or reuse this material. On the other hand, other divisions or units of the same company or outside companies may be purchasing this same material as a feedstock to their manufacturing operations. By selling the recovered material from the generating company to a user company at a price reflecting the savings to both companies, then (i) the seller doesn't have the expense of disposing of the material and (ii) the buyer gets some economic incentive to use the recovered material rather than new material purchased in the open market.

Waste exchanges can be effective for laboratory chemicals that are no longer needed for the purpose for which they were originally purchased. They may be leftovers from completed or terminated projects or merely excess inventory. If they are effectively collected, labeled, and stored in the original containers in a convenient place accessible to potential users, they can be used by personnel other than the original purchasers in preference to making new purchases. This system works well and saves money when used inside a single corporation having large laboratories. This is largely because there is no question about what company receives the financial benefits of the operation. However, it does require a control system to provide assurance that identity and purity of the chemicals are correct and that unstable materials are not included in the chemical storage inventory.

Waste exchanges between companies are usually worked out on single items which pose no threat to either company in terms of disclosure of trade secrets or proprietary process technology, or exposure to sanctions under anti-trust laws against cooperation. These factors along with the problems of negotiating equitable prices for recovered material as feedstocks have prevented waste exchange between companies from achieving very much of its potential. However, DuPont (1991) has offered a resolution to this problem by offering for sale in the open market chemicals recovered as by-products from waste streams generated in chemical manufacturing. This arm's length approach may be the direction that inter-company waste recycling takes in the future. In spite of the institutional obstacles to waste exchange, its great potential for waste minimization and financial return should lead to increased application of this technique.

Waste Streams

Waste streams are any unused solid or liquid by-products of a process, and they can also be exploited for ethanol production.

Waste streams are often inexpensive to obtain, and in many instances, they have a negative value attributable to current disposal costs. Some principal waste streams currently under consideration include mixed paper from municipal solid waste, cellulosic fiber fines from recycled paper mills, bagasse from sugar manufacture, corn fiber, potato waste, and citrus waste, sulfite waste liquors, and hydrolysis streams from fiber board manufacture. Each waste stream has its own unique characteristics, and they generally vary from one source or time to another.

Waste streams with low lignin content and smaller particle size are easier to deal with than those with higher lignin contents and larger particle sizes. Waste paper that has been treated by a chemical pulping process is much more readily converted than is native wood or herbaceous residue.

Waste Tires

A waste tire (often referred to as a scrap tire) is a tire that is no longer mounted on a vehicle and is no longer suitable for use as a vehicle tire due to wear, damage, or deviation from the manufacturer's original specifications. A waste tire includes a repairable tire, scrap tire, and altered waste tire, but does not include a tire-derived product, crumb rubber, or a used tire that is organized for inspection and resale by size in a rack or a stack.

More specifically, a waste tire is a tire that is no longer mounted on a vehicle and is no longer suitable for use as a vehicle tire due to wear, damage, or deviation from the original specifications issued by the manufacturer. Therefore, a waste tire is a tire that is not brand new, nor is it mounted on a vehicle, and it is not stored in a manner for display and sale that allows for inspection of the tread. A waste tire is not intended for use on a vehicle again.

Tire recycling is the process of recycling waste tires that are no longer suitable for use on vehicles due to wear or irreparable damage. These tires are a challenging source of waste, due to the large volume produced, the durability of the tires, and the components in the tire that are ecologically problematic. Because tires are durable and non-biodegradable, they can consume valued space in landfills. Newer technology, such as pyrolysis and devulcanization, has made tires suitable targets for recycling despite their bulk and resilience. Aside from use as fuel, the main end use for tires remains ground rubber.

Waste Vegetable Oil

Waste vegetable oil (WVO) is grease from the nearest fryer which is filtered and used in modified diesel engines, or converted to biodiesel through the process of transesterification and used in any old diesel car.

Many advocates suggest that waste vegetable oil is the best source of oil to produce biodiesel, but since the available supply is drastically less than the amount of petroleum-based fuel that is burned for transportation and home heating in the world, this local solution does not scale well.

However, in an effort to reduce dependency on petroleum-based fuels, there is an interest in installing conversion kits which allow diesel engines to burn waste vegetable oil along with standard diesel or biodiesel fuel. Such vehicles are usually termed *grease cars*.

A grease car uses filtered vegetable oil, often obtained at little to no cost from local restaurants, to power a slightly modified diesel engine. The primary modifications made to a grease car are a new storage tank for the vegetable oil, additional fuel filters, and a heater to bring the oil up to operating temperature.

A grease car gets approximately the same mileage as a regular diesel car, and the emission levels are a marked improvement over other types of vehicles, making it a phenomenal tool for reducing pollution. Greenhouse gas

emissions can drop anywhere from 78 to 87% overall when you convert a diesel car to a grease car. While they still emit nitrogen oxides and carbon monoxide, grease cars are carbon neutral.

A grease car may also require standard diesel fuel during the start-up process since the vegetable oil may not readily ignite at lower air temperatures until warmed by a heater unit.

Water

Water (H_2O) is a polar inorganic compound that is (at room temperatures) a tasteless and odorless liquid which is almost colorless with a gentle suspicion of blueness. It is often considered to be a universal solvent because of the ability to dissolve many substances and is, therefore, also considered to be the *solvent of life*. In fact, natural water (i.e., water as it exists in nature) invariably includes various dissolved substances, and special process steps are required to obtain chemically pure water.

Water is the only common substance to exist as a gas (water vapor or steam), solid (ice), and liquid in normal terrestrial conditions. The addition or removal of heat can cause phase transitions such as freezing to a solid (liquid water to ice), melting (ice to liquid water), vaporization (liquid water to vapor), condensation (vapor to liquid water), sublimation (ice to vapor), and deposition (vapor to ice).

Water differs from most liquids in that it becomes less dense as it freezes. At 1 atmosphere pressure (14.7 psi), water reaches a maximum density of $1,000 \text{ kg/m}^3$ (62.43 lb/ft^3) at 3.98°C (39.16°F). The density of ice is 917 kg/m^3 (57.25 lb/ft^3) which represents an expansion on the order of 9% than can exert pressure on pipes. In a lake or ocean, water at 4°C (39°F) sinks to the bottom and ice forms on the surface and floats on the liquid water. This ice insulates the water below, preventing it from freezing solid which assists in the survival of aquatic organisms.

Overall, water is a unique chemical that is a major component of all living things and is anomalous in many of the chemical and physical properties (Eisenberg and Kauzmann, 1969.; Gerstein and Levitt, 1998; Sharp, 2001). Some of properties are essential for life, while others have effects on the size and shape of living organisms, how they work, and the physical limits or constraints within which they must operate. Moreover, many of the basic physical properties of water can be explained in molecular and structural terms which is relevant to the behavior of water as the properties pertain to the aquasphere. In particular, it is the readiness of water to particular in hydrogen bonding interactions (Eisenberg and Kauzmann, 1969., 1969; Gerstein and Levitt, 1998. Sharp, 2001).

Water is an important aspect of the Earth system and, like any of the components of the Earth system, can be polluted by any type of energy or energy source. It is, therefore, of necessity to know the properties of water in order to protect any of the water systems of the Earth.

The study of water (hydrology) is divided into a number of subcategories, the most prominent of which are (i) limnology, which is the branch of the science dealing with the characteristics of fresh water, including biological properties as well as chemical and physical properties, and (ii) oceanography, which is the science of the ocean and its physical and chemical characteristics.

Water is an inorganic, transparent, tasteless, and odorless chemical substance and is a major component of all living things, and it is anomalous in many of the physical and chemical properties. Some of the properties are essential for life, while other properties have significant (often detrimental) effects on the size and shape of living organisms, how the organisms work, and the constraints within which the organisms must operate. Many of unusual properties of water occur because of the attraction among its polar molecules. The properties of water include cohesion, adhesion, capillary action, surface tension, the ability to dissolve many substances, and high specific heat.

A water molecule is made up of two hydrogen atoms bonded to an oxygen atom (H_2O) and is often referred to as a bent molecule (in a tetrahedral configuration) in which each end of a water molecule has a slight electric charge giving the molecule polarity.

In some scientific circles, because of the tetrahedral configuration of the molecule, water has been jokingly referred to as tetrahedral soup.

This uneven distribution of charges (polarity) across a molecule makes one end positive (H) and the other negative (O). The positive hydrogen ends of one water molecule attract the negative oxygen ends of nearby water molecules causing them to associate, and this attraction causes water molecules to form temporary bonds (hydrogen bonds) that can break easily. Also, water is an amphoteric molecule insofar as it can exhibit the properties of an acid or a base, depending on the pH of the aqueous solution. Water readily produces both hydrogen ions (H^+) and hydroxyl ions (OH^-), and because of the amphoteric character nature, water undergoes self-ionization. The product of the concentrations of hydrogen ions and hydroxyl ions is a constant, so the respective concentrations of these ions are inversely proportional to each other.

The tendency for water molecules is to form weak hydrogen bonds (cohesion), and because of cohesion, water molecules remain joined together as they move within or between the cells of organisms. A special example of cohesion is surface tension which is the force that acts on the particles at the surface of a liquid. In liquid water, each water molecule is pulled in all directions by other water molecules, but at the surface of the water, the attractive force of other water molecules pulls only downward and sideways. This force causes molecules at the surface to be held more tightly together, forming a type of skin at the surface of the water. Small insects, such as water striders, can walk on water by taking advantage of this surface tension. Also, it is the surface tension that causes raindrops to form round beads when they fall onto a glass surface.

Water molecules are not attracted only to each other but have a tendency to associate with other substances through adhesion. Adhesion allows water to stick to the sides of blood vessels or to the vascular tubes in plants. Both cohesion and adhesion allow water to move in one continuous column from the roots to the leaves of a plant. This upward movement (capillary action) is the result of both cohesion of the water molecules to each other and adhesion to the sides of the glass. Capillary action is the combined force of attraction among water molecules and with the molecules of surrounding materials causing a liquid to climb upward against the force of gravity. Thus, capillary action allows water to move through materials with pores inside and also causes water molecules to cling to the fibers of material like paper and cloth.

Water is often referred to as the universal solvent because of the ability to dissolve more substances than any other known solvent. The main property of water that makes it such a good solvent is its polarity, and, as a result, the charged ends of the water molecule attract the molecules of other polar substances. (Like dissolves like.) Water can dissolve substances such as sugars (carbohydrates, $C_6H_{12}O_6$), bleach (sodium hypochlorite, $NaOCl$), and salt ($NaCl$). Water can also dissolve gases such as carbon dioxide (CO_2) and oxygen (O_2). Moreover, the ability of water to dissolve many substances allows water to deliver essential nutrients to cells in plants, animals, and other organisms. Water dissolves nutrients in food but does not dissolve nonpolar substances such as oil and wax which are water-repellant (hydrophobic).

Thus, water has a number of unique properties (Table W-3) that make it suitable for living organisms and a solvent for many materials. Thus, it is the basic transport medium for nutrients and waste products in life processes (Stollenwerk and Kipp, 1990). But, a point that must not be missed; there is also the very real potential for water to transport toxins.

Table W-3 General properties of water.

Property	Effects and significance
Excellent solvent	Transport of nutrients and waste products.
High dielectric constant	High solubility of ionic substances.
Maximum density at 4°C	Ice floats; vertical circulation restricted in stratified bodies of water.
High heat of evaporation	Determines transfer of heat and water molecules between the atmosphere and bodies of water.
High latent heat of fusion	Temperature stabilized at the freezing point of water.
High heat capacity	Stabilization of temperatures of organisms.

The high dielectric constant of water affects its solvent properties, in that most ionic materials are dissociated in water. In addition, water has a high heat capacity; thus, a relatively large amount of water is required to change appreciably the temperature of a mass of water. Hence, a body of water can have a stabilizing effect upon the temperature of nearby geographic regions.

The high heat capacity of water also prevents sudden changes of temperature in large bodies of water and thereby protects aquatic organisms from the shock of abrupt temperature variations. The high heat of vaporization of water (585 cal/g at 20°C, 68°F) also stabilizes the temperature of bodies of water and influences the transfer of heat and water vapor between bodies of water and the atmosphere.

Water has its maximum density at 4°C (39°F), a temperature above its freezing point (0°C, 32°F). The fortunate consequence of this fact is that ice floats, so that few large bodies of water ever freeze solid. Furthermore, the pattern of vertical circulation of water in lakes, a determining factor in the chemistry and biology of water, is governed largely by the unique temperature-density relationship of water. Thus, the physical condition of a body of water strongly influences the chemical and biological processes that can occur in water.

Surface water occurs primarily in streams, lakes, and reservoirs. Lakes may be classified as oligotrophic, eutrophic, or dystrophic, an order that often parallels the life of the lake (Table W-4).

Table W-4 General types of lakes.

Types of lakes	Description
Based on nutrients	
Oligotrophic lake	Low nutrient concentrations.
Eutrophic lake	Oversupply of nutrients like nitrogen and phosphorus; usually a result of agricultural run-off or discharge of municipal sewage.
Dystrophic lake	Low pH, high humic acid content, and brown waters.
Based on origin	
Volcanic lake	Receives water from magma after volcanic eruptions; has highly restricted biota.
Endemic lake	Very ancient, deep, and have endemic (native to that area) fauna.
Artificial lake	Created due to construction of a dam.
Based on of salinity	
Fresh water lake	Low concentration of salts.
Salt water lake	High concentration of salts.
Meromictic lake	Rich in salts; permanently stratified.
Desert salt lake	Occur in arid regions; high salt concentrations due to high evaporation.

Oligotrophic lakes are deep, generally clear, deficient in nutrients, and without much biological activity. Eutrophic lakes have more nutrients, support more life, and are more turbid. Dystrophic lakes are shallow, clogged with plant life, and normally contain colored water with a low pH. Estuaries constitute another type of body of water, consisting of arms of the ocean into which streams flow. The mixing of fresh and salt water gives estuaries unique chemical and biological properties. Estuaries are the breeding grounds of much marine life, which makes the preservation of such systems an important aspect of water protection.

Wetlands are flooded areas in which the water is shallow enough to enable growth of bottom-rooted plants. Wet flatlands are areas where mesophytic vegetation is more important than open water and which are commonly developed in filled lakes, glacial pits, and potholes, or in poorly drained coastal plains or flood plains. The term swamp is usually applied to a wetland where trees and shrubs are an important part of the vegetative association, and the term bog implies lack of solid foundation. Some bogs consist of a thick zone of vegetation floating on water.

Unique plant associations characterize wetlands in various climates and exhibit marked zonation characteristics around the edge in response to different thicknesses of the saturated zone above the firm base of soil material. Coastal marshes covered with vegetation adapted to saline water are common on all continents.

Some constructed reservoirs are similar to lakes, while others differ a great deal from them. Reservoirs with a large volume relative to their inflow and outflow are called storage reservoirs. Reservoirs with a large rate of into the reservoir and out of the reservoir (flow-through) compared to the reservoir volume are run-of-the-river reservoirs. The physical, chemical, and biological properties of water in the two types of reservoirs may vary appreciably. Also, water in storage reservoirs more closely resembles lake water, whereas water in run-of-the-river reservoirs is much like river water.

Impounding water in reservoirs may have some profound effects upon water quality, and these changes result from factors such as different velocities, changed detention time, and altered surface-to-volume ratios relative to the streams that were impounded. Some resulting beneficial changes due to impoundment are a decrease in the level of organic matter, a reduction in turbidity, and a decrease in hardness (calcium and magnesium content).

Some detrimental changes are lower oxygen levels due to decreased reaeration, decreased mixing, accumulation of pollutants, lack of a bottom scour produced by flowing water scrubbing a stream bottom, and increased growth of algae. Algal growth may be enhanced when suspended solids settle from impounded water, causing increased exposure of the algae to sunlight. Stagnant water in the bottom of a reservoir may be of low quality. Oxygen levels frequently go to almost zero near the bottom, and hydrogen sulfide is produced by the reduction of sulfur compounds in the low oxygen environment. Insoluble iron (Fe^{3+}) species are reduced to soluble iron (Fe^{2+}) species which must be removed prior to use of the water.

The unique temperature-density relationship of water results in the formation of distinct layers (stratification) within non-flowing bodies of water. During the summer, a surface layer (epilimnion) is heated by solar radiation and, because of its lower density, floats upon the bottom layer (hypolimnion). This phenomenon is called thermal stratification. When an appreciable temperature difference exists between the two layers, they do not mix but behave independently and have different chemical and biological properties. The epilimnion, which is exposed to light, may have a heavy growth of algae. As a result of exposure to the atmosphere and (during daylight hours) because of the photosynthetic activity of algae, the epilimnion contains relatively higher levels of dissolved oxygen and generally is aerobic. In the hypolimnion, bacterial action on biodegradable organic material may cause the water to become anaerobic. As a consequence, chemical species in a relatively reduced form tend to predominate in the hypolimnion.

The shear-plane, or layer between epilimnion and hypolimnion (the thermocline) and during the autumn, when the epilimnion cools, a point is reached at which the temperatures of the epilimnion and hypolimnion are equal. This disappearance of thermal stratification causes the entire body of water to behave as a hydrological unit, and the resultant mixing (the overturn) generally occurs in the spring. During the overturn, the chemical and physical characteristics of the body of water become much more uniform, and a number of chemical, physical, and biological changes may result. Biological activity may increase from the mixing of nutrients. Changes in water composition during overturn may cause disruption in water treatment processes (Cheremisinoff, 1995).

An increasing amount of attention has been given to thermal pollution, the raising of the temperature of a waterway by heat discharged from the cooling system or effluent wastes of an industrial installation. This rise in temperature may sufficiently upset the ecological balance of the waterway to pose a threat to the native life-forms. This problem has been especially noted in the vicinity of nuclear power plants. Thermal pollution may be combated by allowing wastewater to cool before emptying into the waterway which is often accomplished in large cooling towers.

The chemistry and biology of the oceans are unique because of the high salt content, depth, and other factors. The environmental problems of the oceans have increased greatly in recent years because of ocean dumping of pollutants, oil spills, and increased utilization of natural resources from the oceans. Moreover, many of the pollutants have a considerable lifetime in the ocean (Figure 4.3).

In many cases, oceans, rivers, and lakes have become polluted from discharges of liquid wastes from residential, commercial, and industrial sources, and many of these bodies of water have been reclaimed because of the construction of new wastewater treatment facilities. Both physical-chemical and biological processes are used to remove organic matter from the liquid wastewater stream. It is this organic matter that causes a depletion of oxygen *in rivers and lakes, with consequent anaerobic conditions leading to fish kills and noxious odors.*

The physical-chemical and biological processes remove an abundance of the organic matter, along with floatable scum and grease from the waste stream. Chemical disinfection inactivates bacteria, viruses, and protozoa in the waste stream. The physical and chemical processes used for removing solids from the waste stream include screening, sand and grit separation, chemical coagulation, and plain sedimentation. Biological processes include activated sludge, contact towers, and biological discs. The application of these treatment processes to residential, commercial, and industrial wastewaters has reduced the pollution load on many rivers, lakes, and harbors. There do remain, however, cases of large metropolitan areas that have not completed their cleanup campaigns, and in many other regions, discharges of untreated mixtures of sanitary wastes and storm waters occur during heavy rains.

These discharges emanate from large conduits that carry both sanitary and storm wastes. The impurities that run off the land during a storm mix with the sanitary wastes in the pipes, and the quantity of wastewater overtaxes the carrying capacity of the conduits. A portion of this mixture flows into the nearest body of water before it can reach the wastewater treatment facility. Where wastewater must be discharged into a lake or into a dry stream, a higher level of treatment must be employed, including removal of nutrients and colloidal matter.

Water-Cooled Vibrating Grate Boiler

A water-cooled vibrating grate is a boiler grate made up of a tuyere grate surface mounted on a grid of water tubes interconnected with the boiler circulation system for positive cooling; the structure is supported by flexing plates allowing the grid and grate to move in a vibrating action; ash is automatically discharged.

The water-cooled vibrating grate (HVB) was developed for combustion of all types of biomass, peat, and refuse-derived fuels. It is preferred that the fuel have little or no mineral matter, i.e., low ash production.

The grate consists of two or four panel walls mounted on leaf springs. The panels are placed at an angle of 6° to the horizontal, and each panel is activated by a vibrating unit via a connecting rod. The panels are vibrated in pairs in counter-phase in order to balance external forces.

The fuel moves from the top of the grate to the lower end toward the slag hopper. The vibrating frequency is adjustable by means of a v-belt wheel. The start/stop sequence is controlled and can be freely adjusted to the condition of the fuel. Commonly used limits depend on the properties and condition of the fuel.

There are no mechanical joints or moving parts under the vibration grate that need lubrication. As it is thus only the strength of the construction materials that set the limit, the under-grate air can be preheated to 300°C (570°F) without any problems.

Water Cycle

The water cycle describes the means by which water evaporates from the surface of the Earth, rises into the atmosphere, cools, condenses to form clouds, and falls again to the surface as precipitation. This system of the cycling of water is intimately linked with energy exchanges among the atmosphere, the ocean, and land that determine the climate of the Earth and cause much of natural climate variability. For example, approximately 75% of the energy (or heat) in the global atmosphere is transferred through the evaporation of water from the surface of the Earth. On land, water evaporates from the ground, mainly from soils, plants (through transpiration), lakes, and streams. In fact, approximately 15% of the water entering the atmosphere is from evaporation from the land surfaces and evapotranspiration from plants which (i) cools the surface of the Earth, (ii) cools the lower atmosphere, and (iii) provides water to the atmosphere to form clouds.

The major physical components of the global water cycle include (i) the evaporation from the ocean and land surfaces, (ii) the transport of water vapor by the atmosphere, precipitation onto the ocean and land surfaces, (iii) the net atmospheric transport of water from land areas to ocean, and (iv) the return flow of fresh water from the land back into the ocean. The additional components of oceanic water transport are few, including the mixing of fresh water through the oceanic boundary layer, transport by ocean currents, and sea ice processes.

Water Cycle

Water is practically everywhere on Earth. Moreover, it is the only known substance that can naturally exist in three phases as (i) a gas, (ii) a liquid, and (iii) a solid within the relatively small range of air temperatures and pressures found at the surface of the Earth. Water is essential for the existence of life on the Earth and acts as a conjunction between the major parts of the climate system of the Earth— air, clouds, the ocean, lakes, vegetation, snowpack, and glaciers.

Water vapor has a huge influence on the Earth insofar as water vapor is a powerful greenhouse gas, and it is a major driver of the weather and climate systems of the Earth; it travels around the globe, transporting latent heat – latent heat is heat obtained by water molecules as they transition from liquid or solid to vapor; the heat is released when the molecules condense from vapor back to liquid or solid form, creating cloud droplets and various forms of precipitation.

The water cycle is an illustration of the continuous movement of water within the Earth and atmosphere. The cycle is a complex system that includes many different processes. Liquid water evaporates into water vapor, condenses to form clouds, and precipitates back to Earth in the form of rain and snow. Water in different phases moves through the atmosphere (transportation). Liquid water flows across land (runoff), into the ground (infiltration and percolation), and through the ground (groundwater). Groundwater moves into plants (plant uptake) and evaporates from plants into the atmosphere (transpiration). Solid ice and snow can turn directly into gas (sublimation). The opposite can also take place when water vapor becomes solid (deposition).

One aspect of the water cycle – precipitation – is a vital component of how water moves through the water cycle, connecting the atmosphere, the ocean, and the land. Knowing where it rains, how much it rains, and the character of the falling rain, snow, or hail affords an understanding of the impact of precipitation on streams and rivers as well as surface runoff and groundwater.

The water cycle also illustrates the manner in which water evaporates from the surface of the Earth, rises into the atmosphere, cools and condenses into rain or snow in clouds, and falls again to the surface of the Earth as precipitation. The water falling on land collects in rivers and lakes, soil, and porous layers of rock, and much of it flows back into the oceans, where it will once more evaporate. The cycling of water in and out of the atmosphere is a significant aspect of the weather patterns of the Earth.

Moreover, the water cycle has no starting point, but, as a context for this text, the Sun, which drives the water cycle, heats the water in the oceans, and causes some of the water to evaporates (as vapor) into the air. Ice and snow can sublime directly (by omitting the liquid phase) into water vapor. Rising air currents take the vapor up into the atmosphere, along with water from evapotranspiration, which is water that is transpired from plants and evaporated from the soil. The vapor rises into the air where cooler temperatures cause the water vapor to condense into clouds.

Air currents move clouds around the globe; cloud particles collide, grow, and fall out of the sky as precipitation. Some of the precipitation falls as snow and can accumulate as ice caps and glaciers, which can store frozen water for thousands of years. The snowpack in warmer climates often thaw and melt when spring arrives, and the melted water flows overland as snowmelt.

Most of the precipitation falls back into the oceans or on to land, where, due to gravity, the precipitation flows over the ground as surface runoff. A portion of the runoff enters rivers in valleys in the landscape, with streamflow moving water toward the oceans. On the other hand, some of the runoff, and groundwater seepage, accumulate and are stored as freshwater in lakes, but not all of the runoff flows into rivers, though. Much of the runoff soaks into the ground (infiltration), some of which infiltrates deep into the ground and replenishes aquifers (saturated subsurface rock formation), which store considerable amounts of water for long periods of time. Some infiltration stays close to the land surface and can seep back into surface-water bodies (and the ocean) as groundwater discharge, and some groundwater finds openings in the land surface and emerges as freshwater springs.

Over time, the water continues to move – some to reenter the ocean, where the water cycle continues as outlined above.

Water Gas

Water gas (carbureted blue gas) is a mixture of carbon monoxide and hydrogen formed by the action of air and then steam on hot coal or coke and enriched with hydrocarbon gases from the pyrolysis of oils.

On the other hand, semi-water gas is a mixture of water gas and producer gas that is made by passing a mixture of air and steam through heated coke. The heat generated when producer gas is formed keeps the temperature of the coke high enough to allow water gas to be formed.

The Lowe's water gas process is a process by which large amounts of hydrogen gas could be generated for residential and commercial use in heating and lighting. This gas provides a more efficient heating fuel than the common coal gas, or coke gas, which was used in municipal service. The process uses the water-gas shift reaction:

The process was discovered by passing high-pressure steam over hot coal, the major source of coke gas. Lowe's process improved upon the chimney systems by which the coal could remain superheated, thereby maintaining a consistently high supply of the gas. The reaction produced carbon dioxide and hydrogen, which, after a process of cooling and scrubbing, produced hydrogen gas.

See also: Gasification, Water-Gas Shift Reaction.

Water-Gas Shift Reaction

Even though the water-gas shift reaction is not classified as one of the principal gasification reactions, this reaction cannot be omitted in the analysis of chemical reaction systems that involve synthesis gas. Among all reactions involving synthesis gas, this reaction equilibrium is least sensitive to the temperature variation. In other words, its equilibrium constant is least strongly dependent upon the temperature. Therefore, this reaction equilibrium can be reversed in a variety of practical process conditions over a wide range of temperatures. Water-gas shift reaction in its forward direction is mildly exothermic as:

Even though all the participating chemical species are in forms of gas, scientists have not only believed that this reaction predominantly takes place at the heterogeneous surfaces of coal, but also that the reaction is catalyzed by carbon surfaces. Since the water-gas shift reaction is catalyzed by many heterogeneous surfaces and the reaction can also take place homogeneously as well as heterogeneously, a generalized understanding of water-gas shift reaction has been difficult to achieve. Even the kinetic rate information in the literature may not be immediately useful or applicable to a practical reactor situation.

Syngas product from a gasifier contains a variety of gaseous species other than carbon monoxide and hydrogen. Typically, they include carbon dioxide, methane, and water (steam). Depending upon the objective of the next processing scheme, the product composition of syngas may need to be preferentially readjusted. If the objective of the gasification were to obtain a high yield of methane, it would be preferred to have the molar ratio of hydrogen to carbon monoxide at 3:1, based on the following methanation reaction stoichiometry:

If the objective of generating syngas were in the synthesis of methanol via vapor-phase low-pressure process, the stoichiometrically consistent ratio between hydrogen and carbon monoxide would be 2:1. In these cases, the stoichiometrically consistent syngas mixture is often referred to as balanced gas, while a syngas composition that is substantially deviated from the principal reaction's stoichiometry is called "unbalanced gas."

If the objective of syngas production were to obtain a high yield of hydrogen, it would be advantageous to yield a higher ratio of H_2/CO by further converting CO (and H_2O) into H_2 (and CO_2) via water-gas shift reaction. However, if the final gaseous product is to be used in the fuel cell applications, carbon monoxide and carbon dioxide must be removed to acceptable levels by a process such as acid gas removal or other adsorption processes. In particular, for hydrogen PEM (proton exchange membrane) fuel cell operation, carbon monoxide must be thoroughly removed from the hydrogen gas.

Water-gas shift reaction is one of the major reactions in steam gasification process, where both water and carbon monoxide are present in ample amounts. Even though all four chemical species involved in the water-gas shift reaction are gaseous compounds at the reaction conditions of most gas processing, the water gas shift reaction, in the case of steam gasification of coal, predominantly takes place heterogeneously, i.e., on the coal solid surface. Water-gas shift reaction is catalyzed by a variety of metallic catalysts. The choice of specific kinds of catalysts has always been dependent upon the desired outcome, the prevailing temperature conditions, composition of gas mixture, and process economics. Many investigators have studied the water-gas shift reaction over a variety of catalysts including iron, copper, zinc, nickel, chromium, and molybdenum. Significant efforts have been spent in developing a robust catalyst system that has superior sulfur tolerance and wider applicable temperature range.

Water Pollutants

Water pollutants can be divided among some general classifications (Table W-5), and water pollution control is closely allied with the water supplies of communities and industries because both generally share the same water resources.

Table W-5 Examples of water pollutants and the effects.

Class of pollutant*	Effect
Acidity, alkalinity, salinity (in excess)	Water quality, aquatic life
Algal nutrients	Eutrophication
Asbestos	Human health
Biochemical oxygen demand	Water quality, oxygen levels
Chemical carcinogens	Incidence of cancer
Crude oil, products, and wastes	Effect of wildlife, health effects
Detergents	Eutrophication, wildlife, health effects
Inorganic pollutants	Toxicity, aquatic biota
Metal-organic combinations	Metal transport
Organic pollutants	Toxicity
Pathogens	Health effects
Pesticides	Toxicity, aquatic biota, wildlife
Polychlorinated biphenyls	Biological effects
Radionuclides	Toxicity
Sediments	Water quality, aquatic biota, wildlife
Sewage	Water quality, oxygen levels
Taste, odor, and color	Health effects, esthetics
Trace Elements	Health, aquatic biota

*Listed alphabetically

There is great similarity in the pipe systems that bring water to each home or business property, and the systems of sewers or drains that subsequently collect the wastewater and conduct it to a treatment facility. Treatment should prepare the flow for return to the environment so that the receiving watercourse will be suitable for beneficial uses such as general recreation, and safe for subsequent use by downstream communities or industries. In considering water pollution, it is useful to keep in mind an overall picture of possible pollutant cycles which involve the major routes of pollutant interchange among the biotic, terrestrial, atmospheric, and aquatic environments.

Water Pollution

Water pollution occurs when harmful substances – often chemicals or microorganisms – contaminate a stream, river, lake, ocean, aquifer, or other body of water, degrading water quality and rendering it toxic to humans or the environment. Thus, water pollution refers to any change in natural waters which may impair further use, caused by the introduction of organic or inorganic substances, or a change in temperature of the water.

Humans have also been polluting water since the early days of civilization. The development of towns and cities in close proximity to rivers also caused the rivers to become polluted by human waste and effluents. Indeed, whole civilizations have disappeared not only because of water shortages resulting from changes in the climate but also because of water-borne diseases, such as cholera and typhoid (Cartwright and Biddiss, 1972). In fact, one can wonder whether or not the castle moat actually protected the inmates from the attackers or whether the diseaseridden moat was fatal to both sides. Also, serious epidemics of water-borne diseases such as cholera, dysentery, and typhoid fever were caused by underground seepage from privy vaults into town wells (James and Thorpe, 1994). Such direct bacterial infections through water systems can be traced back for several centuries, even though the germ or bacterium as the cause of disease was not proved for nearly another century.

In terms of pollution of the oceans (also referred to as marine pollution), a considerable amount of the pollution originates on land – whether it occurs along the coast or inland – and is not always from ships at sea. Contaminants such as chemicals, nutrients, and heavy metals are carried from farms, factories, and cities by streams and rivers into bays and estuaries; from there, they travel out to sea.

See also: Pollutant, Pollution.

Water Removal from Gas Streams

Water is a common impurity in gas streams, and removal of water is necessary to prevent condensation of the water and the formation of ice or gas hydrates ($C_nH_{2n+2} \cdot xH_2O$). As an example from the area of renewable energy, the relative humidity of the gas stream inside the digester is 100%, so the gas is saturated with water vapors. To protect the energy conversion equipment from wear and from eventual damage, water must be removed from the produced the gas stream. The quantity of water contained by the gas stream depends on temperature. A part of the water vapor can be condensed by the cooling of the gas. This is frequently done in the gas pipelines transporting the gas stream from digester to a unit in which the water condensates on the walls of the sloping pipes and can be collected in a condensation separator, at the lowest point of the pipeline.

Water in the liquid phase causes corrosion problems in pipelines and equipment, particularly when carbon dioxide and hydrogen sulfide are present in the gas. The simplest method of water removal (refrigeration or cryogenic separation) is to cool the gas to a temperature at least equal to or (preferentially) below the dew point.

Most of the water associated with natural gas is removed by simple separation methods at or near the wellhead. However, the removal of the water vapor that exists in solution in natural gas requires a more complex treatment. This treatment consists of *dehydrating* the natural gas, which usually involves one of two processes: either absorption or adsorption.

A dehydration process is needed to eliminate water which may cause the formation of hydrates. Hydrates form when a gas or liquid containing free water experiences specific temperature/pressure conditions. Dehydration is the removal of this water from the produced natural gas and is accomplished by several methods. Among these is the use of ethylene glycol (glycol injection) systems as an absorption process. The process removes water and other

solids from the gas stream. Alternatively, adsorption dehydration may be used, utilizing dry-bed dehydrators towers, which contain desiccants such as silica gel and activated alumina, to perform the extraction.

In a majority of cases, cooling alone is insufficient and, for the most part, impractical for use in field operations. Other water removal processes use (i) hygroscopic liquids, such as diethylene glycol or triethylene glycol and (ii) solid adsorbents or desiccants, such as alumina, silica gel, and molecular sieves. Ethylene glycol can be directly injected into the gas stream in refrigeration plants.

The glycol has a chemical affinity for water and removes water from the gas stream. In this process, a liquid desiccant dehydrator serves to absorb water vapor from the gas stream. Essentially, glycol dehydration involves using a glycol solution, usually either diethylene glycol (DEG) or triethylene glycol (TEG), which is brought into contact with the wet gas stream in a *contactor*. The glycol solution will absorb water from the wet gas, and once absorbed, the glycol particles become heavier and sink to the bottom of the contactor where they are removed. The natural gas, having been stripped of most of its water content, is then transported out of the dehydrator. The glycol solution, bearing all of the water stripped from the natural gas, is put through a specialized boiler designed to vaporize only the water out of the solution. The boiling point differential between water (100°C, 212°F) and glycol (204°C, 400°F) makes it relatively easy to remove water from the glycol solution, allowing it to be reused in the dehydration process.

As well as absorbing water from the wet gas stream, the glycol solution occasionally carries with it small amounts of methane and other compounds found in the wet gas. In the past, this methane was simply vented out of the boiler. In addition to losing a portion of the natural gas that was extracted, this venting contributes to air pollution and the greenhouse effect. In order to decrease the amount of methane and other compounds that are lost, flash tank separator-condensers work to remove these compounds before the glycol solution reaches the boiler. Essentially, a flash tank separator consists of a device that reduces the pressure of the glycol solution stream, allowing the methane and other hydrocarbons to vaporize (*flash*). The glycol solution then travels to the boiler, which may also be fitted with air or water-cooled condensers, which serve to capture any remaining organic compounds that may remain in the glycol solution. The regeneration (stripping) of the glycol is limited by temperature: diethylene glycol and triethylene glycol decompose at or before their respective boiling points. Such techniques as stripping of hot triethylene glycol with dry gas (e.g., heavy hydrocarbon vapors, the *Drizo process*) or vacuum distillation are recommended.

Water may be removed from gas streams at the same time as hydrogen sulfide is removed. Moisture removal is necessary to prevent harm to anhydrous catalysts and to prevent the formation of hydrocarbon hydrates (e.g., $C_3H_8 \cdot 18H_2O$) at low temperatures. A widely used dehydration and desulfurization process is the glycolamine process, in which the treatment solution is a mixture of ethanolamine and a large amount of glycol. The mixture is circulated through an absorber and a reactivator in the same way as ethanolamine is circulated in the Girbotol process. The glycol absorbs moisture from the hydrocarbon gas passing up the absorber; the ethanolamine absorbs hydrogen sulfide and carbon dioxide. The treated gas leaves the top of the absorber; the spent ethanolamine-glycol mixture enters the reactivator tower, where heat drives off the absorbed acid gases and water.

Solid adsorbent or solid-desiccant dehydration is the primary form of dehydrating natural gas using adsorption, and usually consists of two or more adsorption towers, which are filled with a solid desiccant. Typical desiccants include activated alumina or a granular silica gel material. Wet natural gas is passed through these towers, from top to bottom. As the wet gas passes around the particles of desiccant material, water is retained on the surface of these desiccant particles. Passing through the entire desiccant bed, almost all of the water is adsorbed onto the desiccant material, leaving the dry gas to exit the bottom of the tower.

Solid-adsorbent dehydrators are typically more effective than glycol dehydrators, and are usually installed as a type of straddle system along natural gas pipelines. These types of dehydration systems are best suited for large volumes of gas under high pressure, and are thus usually located on a pipeline downstream of a compressor station. Two or more towers are required due to the fact that after a certain period of use, the desiccant in a particular tower becomes saturated with water. To regenerate the desiccant, a high-temperature heater is used to heat gas to high temperature. Passing this heated gas through a saturated desiccant bed vaporizes the water in the desiccant tower, leaving it dry and allowing for further natural gas dehydration.

Silica gel (SiO_2) and alumina (Al_2O_3) have good capacities for water adsorption (up to 8% by weight). Bauxite (crude alumina, Al_2O_3) adsorbs up to 6% by weight water, and molecular sieves adsorb up to 15% by weight water. Silica is usually selected for dehydration of sour gas because of its high tolerance to hydrogen sulfide and to protect molecular sieve beds from plugging by sulfur.

In addition to separating any condensate from the wet gas stream, it is necessary to remove most of the associated water. Most of the liquid, free water associated with the extracted gas stream, is removed by simple separation methods; however, the removal of the water vapor that exists in solution in a gas stream requires a more complex treatment. This treatment consists of dehydrating the gas stream, which usually involves one of two processes: either absorption or adsorption.

Moisture may be removed from hydrocarbon gases at the same time as hydrogen sulfide is removed. Moisture removal is necessary to prevent harm to anhydrous catalysts and to prevent the formation of hydrocarbon hydrates (e.g., $C_3H_8 \cdot 18H_2O$) at low temperatures. A widely used dehydration and desulfurization process is the glycolamine process, in which the treatment solution is a mixture of ethanolamine and a large amount of glycol. The mixture is circulated through an absorber and a reactivator in the same way as ethanolamine is circulated in the Girbotol process. The glycol absorbs moisture from the hydrocarbon gas passing up the absorber; the ethanolamine absorbs hydrogen sulfide and carbon dioxide. The treated gas leaves the top of the absorber; the spent ethanolamine-glycol mixture enters the reactivator tower, where heat drives off the absorbed acid gases and water.

Absorption occurs when the water vapor is taken out by a dehydrating agent. Adsorption occurs when the water vapor is condensed and collected on the surface. In a majority of cases, cooling alone is insufficient and, for the most part, impractical for use in field operations. Other more convenient water removal options use (i) *hygroscopic* liquids (e.g., diethylene glycol or triethylene glycol) and (ii) solid adsorbents or desiccants (e.g., alumina, silica gel, and molecular sieves). Ethylene glycol can be directly injected into the gas stream in refrigeration plants.

Water Removal from Gas Streams – Absorption

An example of absorption dehydration is known as *glycol dehydration* – the principal agent in this process is diethylene glycol which has a chemical affinity for water. Glycol dehydration involves using a solution of a glycol such as diethylene glycol (DEG) or triethylene glycol (TEG), which is brought into contact with the wet gas stream in a *contactor*. In practice, absorption systems recover 90 to 99% by volume of methane that would otherwise be flared into the atmosphere.

In the process, a liquid desiccant dehydrator serves to absorb water vapor from the gas stream. The glycol solution absorbs water from the wet gas, and, once absorbed, the glycol particles become heavier and sink to the bottom of the contactor where they are removed. The dry gas stream is then transported out of the dehydrator. The glycol solution, bearing all of the water stripped from the gas stream, is recycled through a specialized boiler designed to vaporize only the water out of the solution. The boiling point differential between water (100°C, 212°F) and glycol (204°C, 400°F) makes it relatively easy to remove water from the glycol solution.

As well as absorbing water from the wet gas stream, the glycol solution occasionally carries with it small amounts of methane and other compounds found in the wet gas. In order to decrease the amount of methane and other compounds that would otherwise be lost, flash tank separator-condensers are employed to remove these compounds before the glycol solution reaches the boiler. The flash tank separator consists of a device that reduces the pressure of the glycol solution stream, allowing the methane and other hydrocarbon derivatives to vaporize (*flash*). The glycol solution then travels to the boiler, which may also be fitted with air- or water-cooled condensers, which serve to capture any remaining organic compounds that may remain in the glycol solution. The regeneration (stripping) of the glycol is limited by temperature: diethylene glycol and triethylene glycol decompose at or even before their respective boiling points. Such techniques as stripping of hot triethylene glycol with dry gas (e.g., heavy hydrocarbon vapors, the *Drizo process*) or vacuum distillation are recommended.

Another absorption process, the Rectisol process, is a physical acid gas removal process using an organic solvent (typically methanol) at subzero temperatures, and characteristic of physical acid gas removal processes, it can purify a gas stream down to 0.1 ppm v/v total sulfur, including hydrogen sulfide (H_2S) and carbonyl sulfide (COS), and carbon dioxide (CO_2) in the ppm v/v range. The process uses methanol as a wash solvent, and the wash unit operates under favorable temperatures below 0°C (32°F). To lower the temperature of the feed gas temperatures, it is cooled against the cold-product streams, before entering the absorber tower. At the absorber tower, carbon dioxide and hydrogen sulfide (with carbonyl sulfide) are removed. By use of an intermediate flash, co-absorbed products such as hydrogen and carbon monoxide are recovered, thus increasing the product recovery rate. To reduce the required

energy demand for the carbon dioxide compressor, the carbon dioxide product is recovered in two different pressure steps (medium pressure and lower pressure). The carbon dioxide product is essentially sulfur-free (hydrogen sulfide-free, carbonyl sulfide-free) and water-free. The carbon dioxide products can be used for enhanced oil recovery (EOR) and/or sequestration or as pure carbon dioxide for other processes.

Water Removal from Gas Streams – Adsorption

Adsorption is a physical-chemical phenomenon in which the gas is concentrated on the surface of a solid or liquid to remove impurities. It must be emphasized that *adsorption* differs from *absorption* in that absorption is not a physical-chemical surface phenomenon but a process in which the absorbed gas is ultimately distributed throughout the absorbent (liquid). Dehydration using a solid adsorbent or solid-desiccant is the primary form of dehydrating the gas stream using adsorption, and usually consists of two or more adsorption towers, which are filled with a solid desiccant. Typical desiccants include activated alumina or a granular silica gel material. A wet gas stream is passed through these towers, from top to bottom. As the wet gas passes around the particles of desiccant material, water is retained on the surface of these desiccant particles. Passing through the entire desiccant bed, almost all of the water is adsorbed onto the desiccant material, leaving the dry gas to exit the bottom of the tower. There are several solid desiccants which possess the physical characteristic to adsorb water from the gas stream. These desiccants are generally used in dehydration systems consisting of two or more towers and associated regeneration equipment.

Molecular sieves – a class of aluminosilicates which produce the lowest water dew points and which can be used to simultaneously sweeten, dry gases and liquids – are commonly used in dehydrators ahead of plants designed to recover ethane and other higher-boiling hydrocarbon derivatives. These plants operate at very cold temperatures and require very dry feed gas to prevent formation of hydrates. Dehydration to -100°C (-148°F) dew point is possible with molecular sieves. Water dew points less than -100°C (-148°F) can be accomplished with special design and definitive operating parameters.

Molecular sieves are commonly used to selectively adsorb water and sulfur compounds from light hydrocarbon streams such as liquefied petroleum gas, propane, butane, pentane, light olefin derivatives, and alkylation feed. Sulfur compounds that can be removed are hydrogen sulfide, mercaptan derivatives, sulfide derivatives, and disulfide derivatives. In the process, the sulfur-containing feedstock is passed through a bed of sieves at ambient temperature. The operating pressure must be high enough to keep the feed in the liquid phase. The operation is cyclic in that the adsorption step is stopped at a predetermined time before sulfur breakthrough occurs. Sulfur and water are removed from the sieves by purging with fuel gas at 205 to 315°C (400 to 600°F).

Solid-adsorbent dehydrators are typically more effective than liquid absorption dehydrators (e.g., glycol dehydrators) and are usually installed as a type of straddle system along gas pipelines. These types of dehydration systems are best suited for large volumes of gas under very high pressure, and are thus usually located on a pipeline downstream of a compressor station. Two or more towers are required due to the fact that after a certain period of use, the desiccant in a particular tower becomes saturated with water. To regenerate and recycle the desiccant, a high-temperature heater is used to heat gas to a very high temperature and passage of the heated gas stream through a saturated desiccant bed vaporizes the water in the desiccant tower, leaving it dry and allowing for further dehydration of the gas stream.

Although two-bed adsorbent treaters have become more common (while one bed is removing water from the gas, the other undergoes alternate heating and cooling), on occasion, a three-bed system is used: one bed adsorbs, one is being heated, and one is being cooled. An additional advantage of the three-bed system is the facile conversion of a two-bed system so that the third bed can be maintained or replaced, thereby ensuring continuity of the operations and reducing the risk of a costly plant shutdown.

Silica gel (SiO_2) and alumina (Al_2O_3) have good capacities for water adsorption (up to 8% by weight). Bauxite (crude alumina, Al_2O_3) adsorbs up to 6% by weight water, and molecular sieves adsorb up to 15% by weight water. Silica is usually selected for dehydration of sour gas because of its high tolerance to hydrogen sulfide and to protect molecular sieve beds from plugging by sulfur. Alumina *guard beds* serve as protectors by the act of attrition and may be referred to as an *attrition reactor* containing an *attrition catalyst* may be placed ahead of the molecular sieves to

remove the sulfur compounds. Downflow reactors are commonly used for adsorption processes, with an upward flow regeneration of the adsorbent and cooling using gas flow in the same direction as adsorption flow.

Solid desiccant units generally cost more to buy and operate than glycol units. Therefore, their use is typically limited to applications such as gases having a high hydrogen sulfide content, low dew point requirements, simultaneous control of water, and hydrocarbon dew points. In processes where cryogenic temperatures are encountered, solid desiccant dehydration is usually preferred over conventional methanol injection to prevent hydrate and ice formation.

Water Removal from Gas Streams – Cryogenics

Another possibility for drying a gas stream is by cooling the gas in electrically powered gas coolers, at temperatures below 10°C (50°F), which allows a lot of humidity to be removed. In order to minimize the relative humidity, but not the absolute humidity, the gas can be warmed up again after cooling, in order to prevent condensation along the gas pipelines.

Thus, cryogenic upgrading makes use of the distinct boiling/sublimation points of the different gases particularly for the separation of carbon dioxide and methane. In the process, the raw (untreated) gas stream is cooled down to the temperatures where the carbon dioxide in the gas condenses or sublimates and can be separated as a liquid or a solid fraction, while methane accumulates in the gas phase. Water and siloxane derivatives are also removed during the cooling of the gas. However, the content of methane in the gas stream affects the characteristics of the gas, i.e., higher pressures and/or lower temperatures are needed to condense or sublime carbon dioxide when it is in a mixture with methane. Cooling usually takes place in several steps in order to remove the different gases in the gas stream individually and to optimize the energy recovery.

As an example, a hot gas stream containing water and carbon dioxide can be upgraded by cooling the gas to 40°C (104°F); most of the water is condensed. The remaining water is removed in the carbon dioxide removal step – the carbon dioxide to be removed from the gas stream to meet the specifications. The final concentration of carbon dioxide in the gas stream is determined by the specification of the Wobbe index. For carbon dioxide removal, considering the high partial pressure of carbon dioxide, both membranes and physical solvents can be chosen, where membranes are at their maximum scale and physical solvents are at their minimum scale (Alderton, 1993; Hall and Lokhandwala, 2004). The main advantage of the cryogenic process is that it is possible to obtain a gas stream with a high methane content of up to 99% v/v. The main disadvantage is that for the upgrading process, it is necessary to use many of technological equipment, especially compressors, turbines, and heat exchangers. This significant demand for additional equipment can make the cryogenic separation process extremely expensive.

Water Removal from Gas Streams – Methanol-Based Processes

Methanol is probably one of the most versatile solvents in the natural gas processing industry. Historically, methanol was the first commercial organic physical solvent and has been used for dehydration, hydrate inhibition, gas sweetening, and liquids recovery. Most of these applications involve low temperature where the physical properties of methanol are advantageous compared with other solvents that exhibit high viscosity problems or even solids formation. Operation at low temperatures tends to suppress the most significant disadvantage of methanol – i.e., high solvent loss. Furthermore, methanol is relatively inexpensive and easy to produce, making the solvent an attractive alternate for gas processing applications.

The use of methanol has been further exploited in the development of the Rectisol process either alone or as toluene-methanol mixtures are used to more selectively remove hydrogen sulfide and move carbon dioxide to the overhead product. Toluene has an additional advantage insofar as carbonyl sulfide (carbonyl sulfide) is more soluble in toluene than in methanol. The Rectisol process was primarily developed to remove both carbon dioxide and hydrogen sulfide (along with other sulfur-containing species) from gas streams resulting from the partial oxidation

of coal, oil, and crude oil residua. The ability of methanol to absorb these unwanted components made it the natural solvent of choice. Unfortunately, at cold temperatures, methanol also has a high affinity for hydrocarbon constituents of the gas streams. For example, propane is more soluble in methanol than is carbon dioxide. There are two versions of the Rectisol process – the two-stage and the once-through. The first step of the two-stage process is desulfurization before shift conversion; the concentrations of hydrogen sulfide and carbon dioxide are approximately 1 and 5% v/v, respectively. Regeneration of the methanol following the desulfurization of the feed gas produces high sulfur feed for sulfur recovery. The once-through process is only applicable for high-pressure partial oxidation products. The once-through process is also applicable when the hydrogen sulfide to carbon dioxide content is unfavorable, in the neighborhood of 1:50.

Recently, a process using methanol has been developed in which there is the simultaneous capability to dehydrate, to remove acid gas, and to control hydrocarbon dew point (Rojey and Larue, 1988; Rojey *et al.*, 1990). The IFPEXOL-1 is used for water removal and hydrocarbon dew point control; the IFPEXOL-2 process is used for acid gas removal. The novel concept behind the IFPEXOL-1 process is to use a portion of the water-saturated inlet feed to recover the methanol from the aqueous portion of the low-temperature separator. That approach has solved a major problem with methanol injection in large facilities, the methanol recovery via distillation. Beyond that very simple discovery, the cold section of the process is remarkably similar to a basic methanol injection process. Modifications to the process include water washing the hydrocarbon liquid from the low temperature separator to enhance the methanol recovery. The IFPEXOL-2 process for acid gas removal is very similar to an amine type process except for the operating temperatures. The absorber operates below -20°F to minimize methanol losses, and the regenerator operates at approximately 90 psi. Cooling is required on the regenerator condenser to recover the methanol. This process usually follows the IFPEXOL-1 process, so excessive hydrocarbon absorption is not as great a problem.

Water System

A water system comprises a drainage basin and its physical, chemical, and biological constituents, including water networks, ecosystems, the built environment, the oceanic and atmospheric systems that govern evaporation and precipitation in the basin, and the source water bodies and terminal lakes or seas into which the water flows. In whichever system water is located, water is a complex system of chemical species that has received considerable study (Eglington, 1975; Jenne, 1979; Melchior and Bassett, 1990). Indeed, the public has been introduced to the issues of water pollution for the past several years, not the least of which is the pollution of Boston Harbor by tea being imported from England which played a significant role in the formation of the United States (Easterbrook, 1995).

Briefly, when rain falls and seeps deep into the earth, filling the cracks, crevices, and porous spaces of an aquifer (basically an underground storehouse of water), it becomes groundwater which is one of the least visible but most important natural resources. Many towns and villages rely upon groundwater – pumped to the surface of the Earth – for drinking water. For some people in rural areas, it is the only freshwater source. Groundwater gets polluted when contaminants—from pesticides and fertilizers to waste leached from landfills and septic systems—make their way into an aquifer, rendering it unsafe for human use. Ridding groundwater of contaminants can vary from difficult to impossible. Once polluted, an aquifer may be unusable for decades, or even thousands of years. Groundwater can also spread contamination far from the original polluting source as it seeps into streams, lakes, and oceans.

On the other hand, surface water covers approximately 70% of the surface of the earth in the form of oceans, lakes, rivers, and streams. In terms of non-oceanic water, surface water from freshwater sources is in danger from various pollutants (Jazib, 2018). In fact, pollution by nutrients, which includes nitrates and phosphates, is the leading type of contamination in the freshwater sources. While plants and animals need these nutrients to grow, they have become a major type of pollutant due to the runoff of farm waste and fertilizer. Municipal and industrial waste discharges into fresh water sources also contribute toxins along with the waste from domestic sources and also from industrial sources, although many countries have laws in place to cease such discharges.

Thus, pollution of a water system occurs when harmful substances – such as chemicals or microorganisms – contaminate a water system (stream, river, lake, ocean, aquifer, or other body of water) causing degrading water quality and rendering the water toxic only to humans but also to other floral and faunal life forms. In fact, water is

uniquely vulnerable to pollution because it can dissolve more substances than any other liquid on the Earth. Toxic substances from farms, towns, and factories readily dissolve into and mix with water leading to water pollution.

See also: Aquasphere.

Water Washing

Water washing, in terms of the outcome, is analogous to washing with potassium carbonate for gas cleaning, and it is also possible to carry out the desorption step by pressure reduction. The absorption is purely physical, and there is also a relatively high absorption of hydrocarbons, which are liberated at the same time as the acid gases.

Wave Energy

Tidal energy (tidal power) has the advantage of being completely predictable: The tides occur with perfect regularity every day. In contrast, waves vary in strength, from a mere ripple to large storm waves. Yet sites with deep, concentrated tidal currents are not common, and waves wash all shores.

Wave energy is the transport of energy by ocean surface waves. Waves are generated by wind passing over the surface of the sea. As long as the waves propagate slower than the wind speed just above the waves, there is an energy transfer from the wind to the waves. Both air pressure differences between the upwind and the lee side of a wave crest, as well as friction on the water surface by the wind, making the water to go into the shear stress, cause the growth of the waves.

Thus, waves are formed due to exchange of power from wind to the water. The winds are formed due to the Sun. The land and water operate as cosmological discharge hoarders; deep sea water is the result of resourcefulness of these. When the water is hot, it is heated and it turns into a form of steam which further turns into air above it. The hot air then ascends and displaces cold air, which falls down to be heated by the water in turn. As a result, air currents are produced. As these currents propel on the surface of the water, the roughness between them causes the water to extend, the result of which is miniature currents. This affects the surface to contact between the water and wind to extend, and gradually larger waves. In addition, waves can also be generated by huge disturbances, which result in tsunamis. Despite the fact that they are uncommon, it is still significant while shaping utmost load energy tool must survive.

Wave height is determined by wind speed, the duration of time the wind has been blowing, fetch (the distance over which the wind excites the waves), and by the depth and topography of the seafloor (which can focus or disperse the energy of the waves). A given wind speed has a matching practical limit over which time or distance will not produce larger waves. In general, larger waves are more powerful, but wave power is also determined by wave speed, wavelength, and water density.

As an alternative energy, wave energy is the capture of the energy of waves for a useful purpose, such as electricity generation, water desalination, or the pumping of water (into reservoirs). Wave power is used synonymously with wave energy, or references the generation of electricity from the energy of waves. As with tidal power, wave power may be considered a form of hydropower whereby the definition of hydropower is expanded to encompass any type of energy gained from the movement of water.

There are at least six different technologies for harvesting wave power which are (i) the attenuator, (ii) the point absorber, (iii) the oscillating wave surge converter, (iv) the oscillating water column, (v) the overtopping device, and (v) the submerged pressure differential.

The attenuator: Long, tubelike floats linked end-to-end by flexible hoses rock as waves pass under them. The motion pressurizes oil, which drives generators. The world's first commercial wave-power farm, along the coast of Portugal, uses this technology and was being installed as of mid-2008. The point absorber is a device in which a float bobs up down on the surface of the waves and a vertical shaft is worked by the motion, pressurizing generators. The oscillating wave surge converter is a device in which a buoy-like arm is tethered to the bottom and waved back and forth like an upside-down pendulum as waves surge past. In the oscillating water column device, a sealed column

with water in its lower portion and air in its upper portion is connected to the sea. Wave action causes the water part of the column to rise and fall, raising and lowering the air and causing air-driven turbines to rotate. The overtopping device allows waves to slosh over the top of a barrier, and the water flows back to the sea through a turbine. The submerged pressure differential uses a drum or tube along which a piston moves is anchored to the ocean floor not far below the surface. Water pressure on the piston varies as waves pass above, causing it to move back and forth in the shaft.

It is approximated that the entire power of waves broke on the seashore is approximately 2-3 terawatts. The best possible locations for wave energy having density typically 65 MW solitary mile of seashore, or 70 kW of power for every meter of wave peak length. In winters, this number raises up to 170 kW/m and can attain as high as 1 MW/m during storms. In winter, waves possess more energy than in other seasons. It is essential to notice that once a wave is produced, it could voyage greater distances without any loss in energy. This provides waves a total of certainty: yet in phase of modest wind and hence miniature wave produced. Waves generated from distant areas can still be added to energy generation.

See also: Ocean Energy, Tidal Energy.

Weibull Distribution

The speed of the wind is highly variable, and in order to be able to predict the production of a wind turbine, it is necessary to know exactly how often the wind blows strongly. Typically, the wind is measured with an anemometer and the mean wind speed is recorded every 10 minutes, and the resulting data can be sorted into wind speed classes of 1 m/s each. The energy contained in the wind at a certain site may then be expressed by this frequency distribution.

In addition, the Weibull distribution is often a good approximation for the wind speed distribution:

$$f(v) = \frac{k}{A} \left(\frac{v}{A} \right)^{k-1} \exp \left(- \left(\frac{v}{A} \right)^k \right)$$

In this equation, A is the Weibull scale parameter in m/s which is a measure for the characteristic wind speed of the distribution. A is proportional to the mean wind speed. k is the Weibull form parameter which specifies the shape of a Weibull distribution and takes on a value of between 1 and 3. A small value for k signifies very variable winds, while constant winds are characterized by a larger value k.

Thus, the Weibull distribution is often a good approximation for the wind speed distribution. Weibull Analysis is an effective method of determining reliability characteristics and trends using a relatively small sample size of field.

Wellman-Galusha Process

The Wellman-Galusha process has been in commercial use for more than 50 years, and there are two types of gasifiers, which are (i) the standard type of gasifier and (ii) the agitated type of gasifier which can have a rated capacity of an agitated unit may be 25% (or more) higher than that of a standard gasifier of the same size.

The gasifier is water-jacketed and, therefore, the inner wall of the vessel does not require a refractory lining. Agitated units include a varying speed revolving horizontal arm which also spirals vertically below the surface of the coal bed to minimize channeling and to provide a uniform bed for gasification. A rotating grate is located at the bottom of the gasifier to remove the ash from the bed uniformly. Steam and oxygen are injected at the bottom of the bed through tuyeres. Crushed coal is fed to the gasifier through a lock hopper and vertical feed pipes. The fuel valves are operated so as to maintain a relatively constant flow of coal to the gasifier to assist in maintaining the stability of the bed and, therefore, the quality of the product gas.

These are two types of gasifiers, the standard type and the agitated type, and the rated capacity of an agitated unit may be 25% (or more) higher than that of a standard gasifier of the same size. An agitated gasifier is capable of treating volatile caking bituminous coals.

The gasifier is water-jacketed and, therefore, the inner wall of the vessel does not require a refractory lining. Agitated units include a varying speed revolving horizontal arm which also spirals vertically below the surface of the coal bed to minimize channeling and to provide a uniform bed for gasification. A rotating grate is located at the bottom of the gasifier to remove the ash from the bed uniformly. Steam and oxygen are injected at the bottom of the bed through tuyeres.

Crushed coal is fed to the gasifier through a lock hopper and vertical feed pipes. The fuel valves are operated so as to maintain a relatively constant flow of coal to the gasifier to assist in maintaining the stability of the bed and, therefore, the quality of the product gas. The air or oxygen which is injected into the gasifier passes over the top of the water jacket and thereby picks up the steam required for the process. The air-steam mix is introduced into the ash bin section underneath the grate and is then distributed through the grate into the bed, and passes upward through the ash, combustion, and gasification zones. The product gas contains primarily carbon monoxide, carbon dioxide, hydrogen, and nitrogen (if air is injected) which, being hot, dries and preheats the incoming coal before leaving the gasifier.

The product gas is passed through a cyclone, in which fine ash and char particles are removed, and if the sulfur content of the gas is acceptable, it may be used directly. If the sulfur content of the gas is too high, the gas can be scrubbed and cooled in a direct-contact countercurrent water cooler and then treated for sulfur removal. Use of air to support combustion will yield a low heat content gas, but use of oxygen will yield a medium heat-content gas.

See also: Gasification.

Wellman-Lord Process

The Wellman-Lord Process is a regenerable process to remove sulfur dioxide from gas streams without creating a throwaway sludge product. The process reduces stack gas sulfur dioxide concentration to less than 250 ppm v/v and can achieve approximately 99.9% sulfur recovery.

The *Wellman-Lord process* (Figure 312) is a versatile process that relies on the reaction of sulfur dioxide with sodium sulfate to produce sodium bisulfite. The bisulfite solution is next heated in an evaporator, which reverses the reaction, liberating a concentrated stream of sulfur dioxide. The sulfur dioxide can then be converted to either elemental sulfur or sulfuric acid.

After lowering the temperature the bisulfite is converted to the sodium pyrosulfite which has a low solubility and precipitates. Heating reverses the two previously described chemical reactions, and the sodium pyrosulfite is converted to sulfur dioxide and sodium sulfite. The sulfur dioxide can be used for further reactions, and the sulfite is reintroduced into the process.

The process can be divided into two main stages. The first stage is an absorption stage in which the hot flue gases are passed through a pre-scrubber where ash, hydrogen chloride, hydrogen fluoride, and sulfur trioxide (SO_3) are removed. The gases are then cooled and fed into the absorption tower. A saturated solution of sodium sulfite is then sprayed into the top of the absorber onto the flue gases; the sodium sulfite reacts with the sulfur dioxide

forming sodium bisulfite. The concentrated bisulfate solution is collected and passed to an evaporation system for regeneration.

The second stage is a regeneration stage in which the sodium bisulfite is broken down, using steam, to release the sodium sulfite, which is recycled back to the flue gases. The remaining product (the released sulfur dioxide) is converted to elemental sulfur, sulfuric acid, or liquid sulfur dioxide. This system offers a number of advantages over alternative systems, the main one being that the sorbent is regenerated during the combustion process and is continuously recycled.

Initially, the process was based on potassium sulfite, but the economic prognosis was poor and the later version used sodium sulfite. Because of side reactions forming thiosulfate (nonregenerable), there is a small makeup requirement in the form of trona (sodium carbonate).

See also: Gasification.

Wet Air Oxidation

The wet air oxidation process is the oxidation (using air) of dissolved or suspended components in water using oxygen as the oxidizer. The process was developed for destruction of organic contaminants, and, in this process, wastewater is exposed to air under elevated temperature and pressure, thus causing organic compounds to oxidize completely or at least decomposing them into forms that are more easily treated.

In the process, oxidation reactions occur in superheated water at a temperature above the boiling point of water (100°C, 212°F), but below the critical point (374°C, 705°F). The system must be maintained under pressure to avoid excessive evaporation of water. The process is predominately used for treating wastewater (Zimpro process).

Commercial systems typically use a bubble column reactor, where air is bubbled through a vertical column that is liquid full of the hot and pressurized wastewater. Fresh wastewater enters the bottom of the column, and oxidized wastewater exits the top. The heat released during the oxidation is used to maintain the operating temperature. The majority of commercial wet oxidation systems are used to treat industrial wastewaters, such as those containing dissolved sulfides. In particular, the process can be used to increase the biodegradable properties of compounds that are normally refractory (resistant) to biological oxidation.

Wet Gas

A wet gas (or a wet gas stream) is any gas with a small amount of liquid present (not necessarily water but often as higher-boiling hydrocarbon derivatives). In fact, the term wet gas has been used to describe a range of conditions varying from a humid gas which is gas saturated with liquid vapor to a multiphase flow system with a 90% volume of gas. Wet gas is a particularly important concept in the field of flow measurement, as the varying densities of the constituent material present a significant problem. Although the example used here is natural gas, the same rationale is also applied to gas streams produced from alternate energy sources such as biomass and waste.

Using natural gas as the example, wet gas has the same basic composition as dry natural gas, though with additional components. Wet gas contains approximately 85% v/v methane and other constituents such as ethane, propane, butane, and, in some instances hydrocarbon derivative up to and including octane. It is the higher-boiling hydrocarbon constituents that make the gas wet. On the other hand, dry gas is gas that is almost completely methane, with a higher methane content making the gas drier. Dry gas is often found in areas without wet gas but can come from similar regions.

Again, using natural gas as an example of wet gas flows are in the production of natural gas from a formation through. Natural gas is a mixture of hydrocarbon derivatives with quantities of various non-hydrocarbon compounds which exists in either the gaseous phase or the liquid phase or in solution with crude oil in porous rock formations (reservoirs). The amount of hydrocarbon derivatives present in the liquid phase of the wet gas extracted for the reservoir depends on the reservoir temperature and pressure conditions, which change over time as the gas and liquid are removed.

Changes in the liquid and gas content also occur when a wet gas is transported from a reservoir at high temperature and pressure to the surface where it experiences a lower temperature and pressure. The presence and changeability of this wet gas can cause problems and errors in the ability to accurately measure the gas phase flowrate. It is necessary to be able to measure these wet gas flows accurately to quantify production from individual wells and to maximize the use of equipment and resources which will assist with the reduction of costs.

Wet Milling Process

The corn wet milling process separates corn into its four basic components: starch, germ, fiber, and protein. There are several basic steps to accomplish this process.

1. First, the incoming corn is visually inspected and cleaned. Refinery people inspect arriving corn shipments and clean them two or three times to remove cob, dust, chaff, and any other foreign materials before the next processing stage, steeping. Effective screening process can save a great deal of trouble in the subsequent stages.
2. Second, it is steeped to initiate bond breaking of starch and protein. Steeping is typically carried out in stainless steel tanks. Each steep tank (or steeping tank) holds approximately 3,000 bushels of corn soaked in water at 50 °C for 30-40 hours. During steeping, the kernels absorb water, thereby increasing their moisture levels from 15% to 45% by weight and also more than doubling in size. The addition of 0.1 % sulfur dioxide (SO₂) to the water suppresses excessive bacterial growth in the warm environment. As the corn swells and softens, the mild acidity of the steeping water begins to loosen the gluten bonds within the corn and eventually release the starch. A bushel is a unit of volume measure used as a dry measure of grains and produce. A bushel of corn or milo weighs 56 pounds, a bushel of wheat or soybeans weighs 60 pounds, and a bushel of sunflowers weighs 25 pounds.
3. Third, it involves a coarse grind to separate the germ from the rest of the kernel. Germ is the embryo of a kernel of grain. This is accomplished in cyclone separators, which spin the low-density corn germ out of the slurry. Therefore, this cyclone separator is called a germ separator. The germs, which contain approximately 85% of corn's oil, are pumped onto screens and washed repeatedly to remove any starch left in the mixture. A combination of mechanical and solvent processes extracts the oil from the germ. The oil is then refined and filtered into finished corn oil. The germ residue is saved as another useful component of animal feeds. Both corn oil and germ residue are important by-products of this process.
4. As the fourth step, the remaining slurry, consisting of fiber, starch, and protein, is finely ground and screened to separate the fiber from the starch and protein. After the germ separation step described in (3), corn and water slurry goes through a more thorough grinding in an impact or attrition-impact mill to release the starch and gluten from the fiber in the kernel. The suspension of starch, gluten, and fiber flows over fixed concave screens, which catch fiber but allow starch and gluten to pass through. The fiber is collected, slurried, and screened again to reclaim any residual starch or protein, then piped or sent to the feed house as a major ingredient of animal feeds. The starch-gluten suspension, called mill starch, is piped or sent to the starch separators.
5. Starch is separated from the remaining slurry in hydrocyclones. By centrifuging mill starch, the gluten is readily spun out due to the density difference between starch and gluten. Starch is denser than gluten. Separated gluten can be used for animal feeds. The starch, with just 1-2% protein remaining, is diluted, washed 8 to 14 times, re-diluted, and re-washed in hydrocyclones to remove the last trace of protein and produce high-quality starch, typically more than 99.5% pure. Some of the starch is dried and marketed as unmodified cornstarch; some other portion is modified into specialty starches, but most is converted into corn syrups and dextrose. Cornstarch has a variety of industrial and domestic uses. All these are important by-products of the process that make the corn distillers' profitability improve.

6. Sixth, the cornstarch then is converted to syrup, and this stage is called starch conversion step. Starch-water suspension is liquefied in the presence of acid and/or enzymes. Enzymes help convert the starch to dextrose that is soluble in water as an aqueous solution. Treatment with another enzyme is usually carried out, depending upon the desired process outcome. The process of acid and enzyme reactions can be stopped or terminated anytime throughout the process to produce a right mixture of sugars like dextrose and maltose for syrups to meet desired specifications. For example, in some cases, the conversion of starch to sugars can be halted at an early stage to produce low-to-medium sweetness syrups. In other cases, however, the starch conversion process is allowed to proceed until the syrup becomes nearly all dextrose. After this conversion process, the syrup is then refined in filters, centrifuges, or ion-exchange columns, and excess water is evaporated to result in concentrated syrup. Syrup can be sold directly as is, crystallized into pure dextrose, or processed further to produce high-fructose corn syrup.
7. Seventh, syrups can be made into several other products through a fermentation process. Dextrose is one of the most fermentable forms of all of the sugars. Dextrose is also called corn sugar and grape sugar, and dextrose is a naturally occurring form of glucose. Dextrose is better known today as glucose. Following the conversion of starch to dextrose, corn refiners pipe and send dextrose to fermentation units/facilities where dextrose is converted to ethanol by traditional yeast fermentation. Using a continuous process, the fermenting mash is allowed to flow, or cascade, through several fermenters in series until the mash is fully fermented and then leaves the final tank. In a batch fermentation process, the mash stays in one fermenter for approximately 48 hours before the distillation process is initiated. Generally speaking, a continuous mode is more effective with a higher fermenter throughput, whereas a higher-quality product may be obtained from a batch mode.
8. As the eighth step, ethanol separation follows the fermentation step. The resulting broth is distilled to recover ethanol or concentrated through membrane separation to produce other by-products. Carbon dioxide generated from fermentation is recaptured for sale, and the nutrients still remaining in the broth after fermentation are used as components of animal feed ingredients. These by-products also help the overall economics of the corn refineries.

Even though the term by-product was used throughout the process description; co-product may be a better term, since these products are not only valuable but also targeted in the master plan of corn distillers.

Wet Oxidation Processes

The wet oxidation processes are based on reduction-oxidation (Redox) chemistry to oxidize the hydrogen sulfide to elemental sulfur in an alkaline solution containing an oxygen carrier. Vanadium and iron are the two oxygen carriers that are used.

The best example of a process using the vanadium carrier is the Stretford process. The most prominent examples of the processes using iron as a carrier are the LO-CAT process and the SulFerox process. The Stretford process using vanadium finds little use now because of the toxic nature of the vanadium solution, and iron-based processes are more common.

Both the LO-CAT process and the SulFerox process are essentially the same in principle. The SulFerox process differs from the LO-CAT in that the oxidation and the regeneration steps are carried out in separate vessels and sulfur is recovered from the filters, melted, and sent to sulfur storage. Also, the SulFerox process uses a higher concentration of iron chelates (approximately 2 to 4% by weight vs. 0.025 to 0.3% by weight for the LO-CAT process). Both processes are capable of up to 99+% sulfur recovery. However, using the processes for Claus tail gas treating requires hydrolysis of all the sulfur dioxide in the tail gas to hydrogen sulfide because the sulfur dioxide will react with the buffering base potassium hydroxide (KOH) and form potassium sulfate (K₂SO₄) which will consume the buffering solution and quickly saturate it.

Wet Scrubbers

Wet scrubbers are devices that utilize gas-liquid contacting to cool the gas stream, condense high-boiling hydrocarbons, dissolve some constituents, and separate particles from gas streams.

There is a large variety of wet scrubbers; however, all have one of three basic operations: (i) gas-humidification – the gas-humidification process conditions fine particles to increase their size so they can be collected more easily, (ii) gas-liquid contact – one of the most important factors affecting collection efficiency, and (iii) gas-liquid separation – regardless of the contact mechanism used, as much liquid and dust as possible must be removed and when contact is made, dust particulates and water droplets combine to form agglomerates – as the agglomerates grow larger, they settle into a collector.

The cleaned gases are normally passed through a mist eliminator (demister pads) to remove water droplets from the gas stream. The dirty water from the scrubber system is either cleaned and discharged or recycled to the scrubber. Dust is removed from the scrubber in a clarification unit or a drag chain tank. In both systems, solid material settles on the bottom of the tank. A drag chain system removes the sludge and deposits it into a dumpster or stockpile.

Wet scrubbers (spray-tower scrubbers) are categorized by pressure drop as follows: (i) low-energy scrubbers, (ii) low-to-medium-energy scrubbers, (iii) medium-to-high-energy scrubbers, and (iv) high-energy scrubbers. In the simple, gravity-spray-tower scrubber, liquid droplets formed by liquid atomized in spray nozzles fall through rising exhaust gases and dirty water is drained at the bottom.

A type of wet scrubber that has been widely applied to coal gas is the venturi scrubber; gas streams are passed through a tube to contact with water, which is added at the throat. The throat promotes intimate mixing of the gas and liquid, which forms droplets ranging in size from 100 to 1,000 microns, and collects particulates mainly by inertial impaction.

Other wet scrubber designs that might be applied to coal gas are plate scrubbers (sieves, bubble caps, and impingement plates), massive packing (rings, saddles), fibrous packing (plastic, spun glass, fiber glass, and steel wool), centrifugal (cyclone), and directional baffles (louvres, zigzags, disk, and donut).

Wet Scrubbing Systems

Wet scrubbing systems, particularly amine or potassium carbonate systems, are used for the removal of acid gases such as hydrogen sulfide or carbon dioxide. Most systems depend on chemical reaction and can be designed for a wide range of pressures and capacities. They were once widely used to remove carbon dioxide in steam reforming plants, but have generally been replaced by pressure swing adsorption units except where carbon monoxide is to be recovered. Wet scrubbing is still used to remove hydrogen sulfide and carbon dioxide in partial oxidation plants.

Wet scrubbing systems remove only acid gases or heavy hydrocarbons, but they do not remove methane or other hydrocarbon gases; hence, they have little influence on product purity. Therefore, wet scrubbing systems are most often used as a pretreatment step, or where a hydrogen-rich stream is to be desulfurized for use as fuel gas.

Wet Sulfuric Acid Process

The wet sulfuric acid process (WSA process) is one out of several desulfurization processes which, since its introduction in the 1980s, has been recognized as an efficient process for recovering sulfur from various process gasses in the form of commercial-quality sulfuric acid (H_2SO_4).

Wet catalysis processes differ from other contact sulfuric acid processes in that the feed gas still contains moisture when it comes into contact with the catalyst. The sulfur trioxide formed by catalytic oxidation of the sulfur dioxide reacts instantly with the moisture to produce sulfuric acid in the vapor phase to an extent determined by the temperature. Liquid acid is subsequently formed by condensation of the sulfuric acid vapor and not by absorption of the sulfur trioxide in concentrated sulfuric acid, as is the case in contact processes based on dry gases. The concentration of the product acid depends on the $\text{H}_2\text{O}/\text{SO}_3$ ratio in the catalytically converted gases and on the condensation temperature.

The wet catalysis process is especially suitable for processing the wet gasses obtained by the combustion of hydrogen sulfide (H_2S) containing off-gasses. The combustion gasses are merely cooled to the converter inlet temperature of approximately 420 to 440°C (790 to 825°F). To process these wet gases in a conventional cold-gas contact process (DCDA) plant would necessitate cooling the gas to an economically unacceptable extent to remove the large excess of moisture.

The chemistry of the process involves several steps. In the first step, sulfur is burned to produce sulfur dioxide:

Hydrogen sulfide is incinerated to sulfur dioxide:

Sulfur dioxide is then oxidized to sulfur trioxide using oxygen in the presence of a vanadium (V) oxide catalyst:

The sulfur trioxide is hydrated and converted to sulfuric acid (H_2SO_4):

The last step is the condensation of the sulfuric acid to liquid 97-98% sulfuric acid.

Wheat Straw

Wheat is harvested across the United States, and its straw is an ideal agricultural residue for use in paper and paper products. The lignin content is comparable to hardwoods, and it has one of the highest cellulose contents of all of the agricultural fibers. When farmed intensively, wheat straw can be produced at a rate of 50 bushels/acre, yielding 1-3 tons per acre (depending on whether it is dry land or irrigated).

Wheat straw is clearly the most abundant non-wood plant material available for pulp and papermaking in the United States. The amount of wheat straw available for pulp production varies depending on the type of wheat grown, the harvest efficiency, and the amount that must be left on the field to comply with any residue management provisions and regulations.

Straw papers are known to possess good printing qualities and are made from pulp requiring low energy relative to that required to process wood pulp. Technicians have found that wheat straw must be pulped under conditions of less energy and fewer chemicals than wood pulps to maximize pulp yields. To make the strongest product, paper-makers will likely combine some stronger hardwood, kenaf, or hemp pulp with straw pulp.

Wheat straw is one of the major agricultural by-products that is currently not used as industrial raw material on a significant scale except for only a minor portion that is reserved as animal feed, household fuel, or as raw materials for paper industry.

See also: Biomass, Straw.

Willow

Willow has several characteristics that make it ideal for woody crop systems, including high yields, ease of propagation, a broad genetic base, a short breeding cycle, and the ability to resprout after multiple harvests. A sustainable system has been devised for willow biomass production by planting unrooted stem cuttings at a density of 4,000-8,000 plants per acre. Willow can achieve high yields, typically reaching 15-25 feet in height in three years, at which

time they can be harvested using modified agricultural equipment that cuts and chips the biomass in one operation. They resprout vigorously from their stumps (coppice) following harvest, with 7 to 8 harvesting cycles possible from an initial planting.

Wind Energy

Wind energy is the form of energy created by wind which is the flow of air on a large scale that is caused by differences in atmospheric pressure. When a difference in atmospheric pressure exists, air moves from the higher to the lower pressure area, resulting in winds of various speeds. Globally, the two major driving factors of large-scale wind patterns (the atmospheric circulation) are the differential heating between the equator and the poles (difference in absorption of solar energy leading to buoyancy forces) and the rotation of the Earth.

In terms of alternative energy, the term wind energy refers to the energy that is harnessed from wind for practical purposes. The term wind power is used synonymously as the conversion of wind energy into a useful form of energy, or more specifically as the generation of electricity from the wind. Among ways in which wind energy can be harnessed are wind turbines to make electrical power, windmills for mechanical power, windpumps for water pumping or drainage, or sails to propel ships.

The energy from the sun does not strike Earth evenly, and, hence, it is to be expected that the predictability of wind current is minimized. The air around the equator absorbs more energy than the air above the poles. This difference causes air, a fluid much like water, to move in currents. Air, like any substance, expands when it is warmed and contracts when it is cooled. Warm air, because it is less dense than cool air, is lighter, so it rises, much like a less-dense piece of wood rises to the top of more-dense water. This effect can be seen by looking at the hot air above a fire, which seems to shimmer as it expands and moves upward, carrying smoke and ash with it. Cold air, because it shrinks, is denser than surrounding warm air, so it sinks. This property explains in part why a freezer generally operates more efficiently when it is placed at the bottom of a refrigerator rather than at the top and why the basement is generally colder than the upper levels of a house.

As warm air rises, colder, heavier air flows in to replace it, causing a current of air, i.e., wind. The rotation of the Earth also plays a role in wind production. If the Earth did not rotate, air heated at the equator would rise only approximately 6 miles (10 kilometers) into the atmosphere and flow toward the North Pole and the South Pole, where it would cool, sink, and return to the equator. Earth's rotation allows winds to circulate in more or less predictable patterns across the Northern Hemisphere and Southern Hemisphere. These winds contain huge amounts of kinetic energy, or the energy contained in any fluid body in motion. Approximately 2% of the solar energy that strikes the Earth is converted into wind. For various reasons, including the revolution of Earth and the features of its terrain, some parts of the Earth have more wind than the others.

Using Wyoming as an example of a state with ample potential for the occurrence of wind (almost daily – the famed Wyoming breeze is a 25 mph wind), there are large wind farms that consist of hundreds of individual wind turbines that are connected to the electric power transmission network. On the other hand, the southeastern United States (compared to Wyoming) has relatively little wind on a regular basis, so this region is generally not considered a good place to place wind turbines. In addition, the storminess in the Southeast would leave wind turbines vulnerable to damage from high winds, during hurricane season, for example. The Rocky Mountain states experience a great deal of wind on a consistent basis, making them better candidates for wind power. The best places to build the turbines are North Dakota, Texas, and Kansas, which by themselves could provide all of the electricity needed in the United States.

Large wind farms consist of hundreds of individual wind turbines that are connected to the electric power transmission network. For new constructions, onshore wind is a relative inexpensive source of electricity, while small onshore wind farms provide electricity to isolated locations. Utility companies increasingly buy surplus electricity produced by small domestic wind turbines. Offshore wind is steadier and stronger than on land, and offshore farms have less visual impact, but the construction and maintenance costs are considerably higher. Floating wind farms are similar to a regular wind farm, but the difference is that they float in the middle of the ocean. Offshore wind farms

can be placed in water up to 130 feet deep, whereas floating wind turbines can float in water up to 2,300 feet deep. The advantage of having a floating wind farm is to be able to harness the winds from the open ocean. Without any obstructions such as hills, trees, and buildings, winds from the open ocean can reach up to speeds twice as fast as coastal areas.

For new constructions, onshore wind is a relatively inexpensive source of electricity, while small onshore wind farms provide electricity to isolated locations. Utility companies increasingly buy surplus electricity produced by small domestic wind turbines. Offshore wind [as evidenced in Ostport (east of Copenhagen, Denmark)] is steadier and stronger than on land, and offshore farms have less visual impact, but the construction and maintenance costs are considerably higher. Floating wind farms are similar to a regular wind farm, but the difference is that they float in the middle of the ocean. Offshore wind farms can be placed in water up to 130 feet (40 meters) deep, whereas floating wind turbines can float in water up to 2,300 feet (700 meters) deep. The advantage of having a floating wind farm is to be able to harness the winds from the open ocean. Without any obstructions such as hills, trees, and buildings, the winds from the open ocean can reach up to speeds twice as fast as coastal areas.

Nighttime wind power is considered the most economical form of electrical power with which to synthesize fuel, because the load curve for electricity peaks sharply during the warmest hours of the day, but wind tends to blow slightly more at night than during the day, so, the price of nighttime wind power is often much less expensive than any alternative.

Wind power offers a number of benefits as an alternative to fossil fuels since it is plentiful, renewable, widely distributed, clean, produces no greenhouse gas emissions during operation, and uses little land. The effects on the environment are generally less problematic than those from other power sources.

However, wind power does have a number of drawbacks. Wind speed does not remain constant, so the supply of power may not always be the same as the demand from consumers. Because many of the best locations for wind turbines are far from urban areas, there are problems with distributing the energy. Also, while wind power is clean and renewable, it also raises environmental concerns. Wind power farms require large stretches of land or have to be placed in environmentally sensitive areas such as deserts or on ridgelines. Many people consider wind farms unsightly, a form of visual pollution. A major environmental concern is the effect of wind farms on patterns of bird migration. Many birds have been killed by flying into wind turbine blades.

The main disadvantage of wind power is the fact that wind is unpredictable, inconsistent, and unsteady, as well as the concern that the full costs of harnessing wind power are not cheap and thus rely on government subsidies to be set up and be competitive. There also are aesthetic concerns, with wind farms being considered by some to be an eyesore, whether restricting the normally picturesque view offshore or in rural areas. Furthermore, there are complaints of noise from turbines, and some communities have been required to shut off their turbines during certain times because of the noise. Older-type wind farms have turbines that spin at high speeds and can thus kill wild birds and bats, although this design has changed so newer wind farms largely avoid such a problem.

In summary, the circulation of wind in the atmosphere (which is not always predictable) is driven by the rotation of the Earth and the incoming energy from the Sun (at the surface, warm air rises and colder air sinks) as well as the circulation of the wind in each hemisphere in three distinct cells (the Ferrel Cell, the Hadley Cell, and the Polar Cell) which help transport energy and heat from the equator to the poles, thereby influencing the climate and the availability of wind for power generation. Thus, changes in the Hadley cell and Walker circulation can result in dramatic climate variations for many regions.

Wind Power

Wind is another renewable energy source that has received much attention in recent years. Wind should almost certainly be used more than it is at present, but for fundamental technological reasons, it will not be the ultimate solution to the electricity generation problem. The idea behind wind power is that wind striking the blades of a large windmill causes them to rotate. This rotational kinetic energy, by a series of gears, drives an electric generator producing electricity.

Wind has some important advantages which are (i) wind power is clearly a renewable energy source, (ii) wind produces electricity in a very clean manner insofar as there are no carbon dioxide emissions or any other harmful pollutants, (iii) a steam cycle is not involved and, therefore the conversion from wind kinetic energy to electricity is reasonably efficient, and (iv) the cost of wind power is within a tolerable range which is particularly true if one were to add in the additional environmental costs of fossil fuel plants.

There are, however, some disadvantages to wind power: (i) the wind does not blow at a constant rate – if it is too weak, not much power is produced or if it is too strong, the blades must turn parallel to the wind to prevent them from spinning too fast and causing mechanical failure, (ii) the power intensity of the wind is very low as compared, for instance, to that in the center of a coal furnace, and producing a significant amount of power requires a large number of windmills spread over a large area.

There are several environmental issues to consider. Windmills tend to be noisy and harmful to birds. There is also the issue of aesthetics. Engineers may find beauty in modern windmills, but the general public tends to view them as unattractive eyesores. Also, they are quite large, with mounting towers on the order of 300 feet high and blades that are on the order of 150 feet in length.

Wind Speed and Wind Gusts

Wind speed is one of the most critical characteristics in wind power generation. In fact, wind speed varies in both time and space, determined by many factors such as geographic and weather conditions – inclusion the Coriolis Force, the Ferrel Cell, the Hadley Cell, and the Polar Cell play a role. Because wind speed is a random parameter, measured wind speed data are usually dealt with using statistical methods.

The diurnal variations of average wind speeds are often described by sine waves. As an example, the diurnal variations of hourly wind speed values have shown the (variable) wavy patterns. Also, based on the wind speed data, it has concluded that the monthly average wind speed in some areas is inversely propositional to the monthly average temperature, i.e., the wind speed is higher in the winter and lower in the summer. In fact, the year-to-year variation of yearly mean wind speeds depends highly on selected locations and thus there is no common correlation to predict it. It is possible, however, to described the wind speed at a site by using the Weibull distribution function which illustrates the probability of different mean wind speeds occurring at the site during a period of time.

One aspect of wind speed that deserves mention here is the phenomenon of wind gust that refers to a sudden increase in wind speed in a relatively small interval of time. In case of sudden turbulent gusts, wind speed, turbulence, and wind shear may change drastically. Reducing rotor imbalance while maintaining the power output of wind turbine generator constant during such sudden turbulent gusts calls for relatively rapid changes of the pitch angle of the blades. However, there is typically a time lag between the occurrence of a turbulent gust and the actual pitching of the blades based upon the dynamics of the pitch control actuator and the large inertia of the mechanical components.

As a result, load imbalances and generator speed, and hence oscillations in the turbine components, may increase considerably during such turbulent gusts, and may exceed the maximum prescribed power output level. Moreover, sudden turbulent gusts may also significantly increase tower fore-aft and side-to-side bending moments due to increase in the effect of wind shear. To ensure safe operation of wind farms, wind gust predictions are desirable.

Wind Turbines

A wind turbine is a machine which converts the power in the wind into electricity. This is in contrast to the older windmill, which is a machine which converts the power of wind into mechanical power. As electricity generators, wind turbines are connected to some electrical network. These networks include battery-charging circuits, residential-scale power systems, isolated or island networks, and large utility grids.

A modern wind turbine is an energy-converting machine to convert the kinetic energy of wind into mechanical energy and in turn into electrical energy. In the recent decades in the latter part of the 20th century, it has been estimated that advances in aerodynamics, structural dynamics, and micrometeorology may contribute to a 5% annual increase in the energy yield of wind turbines. Various wind turbine concepts have been developed and built for maximizing the wind energy output, minimizing the turbine cost, and increasing the turbine efficiency and reliability.

Thus, a wind turbine captures the kinetic energy of wind with, in most cases, two or three blades shaped much like airplane propellers. These blades are attached to a tower that rises at least 100 feet above the ground. At this height, air currents tend to be stronger but less turbulent than they are at ground level. When the wind strikes the blade, the angle and configuration of the blade form a pocket of low pressure on the downwind side of the blade. This low pressure sucks the blade into movement, causing the rotor to turn. Force is added by the high pressure on the upward side of the blade. In aerodynamic theory, this property is called lift. If the blade is designed correctly, lift is stronger than drag, or the slowing force exerted by the wind on the front of the blade.

In wind turbines, lift and drag work together to make the entire mechanism spin like a propeller. In earlier windmills, drag rather than lift was the force that turned the blades. The process is the opposite of that of a fan. With a fan, electricity is used to make wind. With a wind turbine, wind is used to produce electricity. The turning rotor of a wind turbine is connected to a shaft, which is connected to an electric generator. Power can be distributed to users over the electric grid in exactly the same way any other electric power is distributed. The most important feature in the operation of wind turbines is lift. To achieve lift, wind turbine designers have borrowed technology from aircraft designers. In cross section, an airplane wing looks like an irregularly shaped teardrop. The shape is irregular because the wing's bottom is slightly flatter than the top, which is more curved. When a plane flies, its wings slice through the air, creating wind. Because of the curve of the upper surface of the wing, the air has to flow faster to get around the wing. At the same time, the air flows at a lower speed along the bottom surface of the wing. Because of the difference in speed, the air above the wing is less dense; that is, the air pressure is lower than the pressure of the air below the wing. This difference in pressure creates lift perpendicular to the direction of the moving air, allowing the plane to fly. The same principle applies to turbine blades. Unlike airplane wings, wind turbine wings are almost always twisted. The reason they are twisted has to do with another aerodynamic principle, stall. When an airplane wing is tilted back, the wind continues to flow smoothly along the bottom surface, but along the top surface, because of the steeper angle presented to the wind, the air no longer sticks to the wing but swirls around in a circle above it. The result of this swirling is the loss of the low pressure along the upper surface of the wing. Without this low pressure, the plane has no lift and drops like a rock.

Unlike airplane wings, wind turbine blades are constantly rotating, and the speed of the rotation differs along the entire length of the blade. At the precise geometric center, the speed of rotation is zero. This speed steadily increases along the length of the blade until at the tip; the blade can be moving hundreds of feet (meters) per second. This rotation changes the direction at which the wind hits the blade all along its length. In effect, the angle at which the wind hits the blade would be different at each point along the blade if the blade were not twisted. When the blade is twisted, the angle at which the wind hits the blade is the same at each point, and stall is eliminated under normal wind conditions. Excessively high wind speeds can damage rotors, however, so engineers have designed blades that stall when the wind is too strong, and the rotor stops spinning.

There are two main configurations for wind turbines: (i) the horizontal axis turbine and (ii) the vertical axis turbine. The horizontal axis wind turbine (HAWT) and the vertical axis wind turbine (VAWT) are classified or differentiated by the axis of rotation the rotor shafts. Thus, horizontal axis wind turbine (also known as the Darrieus wind turbine) has a horizontal rotor shaft and an electrical generator which is both located at the top of a tower, while the vertical axis wind turbines are designed with a vertical rotor shaft, a generator, and gearbox which are placed at the bottom of the turbine, and a uniquely shaped rotor blade that is designed to harvest the power of the wind no matter which direction it is blowing. Also, the horizontal axis wind turbine rotors are usually classified according to the rotor orientation (upwind or downwind of the tower), hub design (rigid or teetering), rotor control (pitch vs. stall), the number of blades (usually two or three blades), and how they are aligned with the wind (free yaw or active yaw).

A yaw rotation is a movement around the yaw axis of a rigid body that changes the direction it is pointing, to the left or right of its direction of motion. The yaw rate or yaw velocity is the angular velocity of the rotation, or rate

of change of the heading angle when the machine is horizontal. It is commonly measured in degrees per second or radians per second.

A typical modern wind turbine, in a wind farm configuration, and the actual conversion process use the basic aerodynamic force of lift to produce a net positive torque on a rotating shaft, resulting first in the production of mechanical power and then in its transformation to electricity in a generator. Wind turbines, unlike most other generators, can produce energy only in response to the resource that is immediately available. It is not possible to store the wind and use it at a later time. The output of a wind turbine is thus inherently fluctuating and non-dispatchable.

Any system to which a wind turbine is connected must, in some way, take this variability into account. In larger networks, the wind turbine serves to reduce the total electrical load and thus results in a decrease in either the number of conventional generators being used or in the fuel use of those that are running. In smaller networks, there may be energy storage, backup generators, and some specialized control systems. A further fact is that the wind is not transportable: it can only be converted where it is blowing. Historically, a product such as ground wheat was made at the windmill and then transported to its point of use.

Almost all wind turbines use either induction or synchronous generators. These designs entail a constant or nearly constant rotational speed when the generator is directly connected to a utility network. If the generator is used with power electronic converters, the turbine will be able to operate at variable speed.

Many wind turbines installed in grid-connected applications use squirrel cage induction generators (SQIG) which operate within a narrow range of speeds slightly higher than its synchronous speed (a four-pole generator operating in a 60 Hz grid has a synchronous speed of 1,800 rpm). The main advantages of this type of induction generator are that it is rugged, inexpensive, and easy to connect to an electrical network. An increasingly popular option is the doubly fed induction generator (DFIG) which is often used in variable-speed applications.

An increasingly popular option for utility-scale electrical power generation is the variable speed wind turbine. There are a number of benefits that such a configuration offers, including the reduction of wear and tear on the wind turbine and potential operation of the wind turbine at maximum efficiency over a wide range of wind speeds, yielding increased energy capture. Although there are a large number of potential hardware options for variable-speed operation of wind turbines, power electronic components are used in most variable-speed machines currently being designed. When used with suitable power electronic converters, either synchronous or induction generators of either type can run at variable speed.

The principal types of tower design currently in use are the free-standing type using steel tubes, lattice (or truss) towers, and concrete towers. For smaller turbines, guyed towers are also used. Tower height is typically 1 to 1.5 times the rotor diameter, but in any case is normally at least 60 feet. Tower selection is greatly influenced by the characteristics of the site. The stiffness of the tower is a major factor in wind turbine system dynamics because of the possibility of coupled vibrations between the rotor and tower. For turbines with downwind rotors, the effect of tower shadow (the wake created by air flow around a tower) on turbine dynamics, power fluctuations, and noise generation must be considered. For example, because of the tower shadow, downwind turbines are typically noisier than their upwind counterparts.

Wind power has grown to be economically competitive with other forms of power. Although it costs more to generate 1 kilowatt of electricity by wind power than it does with coal- or oil-fired generators, the gap is closing. If 20% of a family's electricity were to come from wind power, the electric bill would be less than \$2 higher per month. The cost of generating wind power has decreased by 85% since 1980.

Wind turbines do not consume water, making them ideal for dry or drought-stricken areas. In contrast, conventional and nuclear power plants consume large amounts of water for cooling and other purposes. Also, wind power is homegrown and not subject to inter-political differences of opinion between countries (as is the case with crude oil) and because wind is free, consumers are not at the mercy of frequently increasing fuel prices.

Wind power is inexhaustible and renewable, in contrast to fossil fuels, and it is clean. Wind power does not contribute to acid rain, smog, global warming, or mercury contamination. It does not release dangerous particles into the air. Also, wind energy is safe. Although the risk exists for industrial accidents in the construction of a wind turbine, the same can be said related to the construction of any facility. The risk that the public will be harmed by a wind-power facility is nearly zero. With nuclear power, the risk of catastrophe is ever present, and with fossil fuel plants, the danger from fire and explosions is high.

On the negative side, wind turbines can be noisy, and engineers are working on ways to quiet the noise. The best method has been to reduce the thickness of the trailing edges of blades. Noise also has been reduced by placing turbines in an upwind rather than a downwind position. The wind hits the blades first, then the tower, rather than the other way around, eliminating the thumping sound that downwind designs make as the blade passes the wind shadow cast by the tower.

Wind farms require a fair amount of land, approximately 60 acres per megawatt of electrolyte produced. However, the turbines themselves plus service roads occupy only approximately 3 acres of the 60 acres. Once the turbines have been built, farmers and ranchers can continue to use the land under them for traditional purposes. Land is difficult to find near larger cities. One solution to this problem is to place wind turbines in shallow waters offshore where possible.

In many regions, the wind is intermittent, meaning that wind power has to be supplemented by other forms of power. Wind-power generation poses additional challenges for power-grid managers, who have to ensure that enough power is available to meet peak demand at all times, even when the wind is not blowing. Thus, not all areas of any country are suitable for wind-power generation. Wind towers and rotors can interfere with radar, posing a potential hazard for air travelers. They can also interfere with television and radio transmission, particularly if they are in the line of sight between the signal source and the receiver. Finally, wind turbines can be a hazard to birds, which sometimes fly into the rotors.

The use of wind power benefits the environment, because this form of energy is clean and it does not consume water. On the other hand, wind power can have harmful effects on the environment. Some environmentalists are concerned about soil erosion, particularly in desert regions, where a thin, fragile layer of topsoil would be disturbed in the construction of turbines, and in the eastern United States, where turbines would be built on mountain ridgelines. Good engineering practices could lessen these effects.

Another potential problem is the effects of wind farms on bird life since birds and bats sometimes fly into wind-turbine blades and are killed; this problem is site specific. Environmentalists are also concerned that wind farms with their service roads and transmission lines may break up the habitat of birds and other wildlife.

Wind Turbines – Classification

Wind turbines can be classified according to (i) the turbine generator configuration, (ii) the airflow path relative to the turbine rotor, (iii) the turbine capacity, (iv) the generator-driving pattern, (v) the power supply mode, and (vi) the location of turbine installation.

When considering the configuration of the rotating axis of rotor blades, modern wind turbines can be classified into the (i) horizontal-axis turbines and (ii) vertical-axis turbines. Many modern commercial wind turbines belong to the horizontal-axis type, in which the rotating axis of blades is parallel to the wind stream. The advantages of this type of wind turbines include the high turbine efficiency, high power density, low cut-in wind speeds, and low cost per unit power output.

The blades of the vertical-axis wind turbines rotate with respect to their vertical axes that are perpendicular to the ground. A significant advantage of the vertical-axis wind turbine is that the turbine can accept wind from any direction and thus no yaw (the twisting or oscillation about a vertical axis) control is needed. Since the wind generator, gearbox, and other main turbine components can be set up on the ground, it greatly simplifies the wind tower design and construction, and consequently reduces the turbine cost. However, the vertical-axis wind turbines must use an external energy source to rotate the blades during initialization. Because the axis of the wind turbine is supported only on one end at the ground, the maximum practical height is limited. Due to the lower wind power efficiency, vertical-axis wind turbines today make up only a small percentage of wind turbines.

Based on the configuration of the wind rotor with respect to the wind flowing direction, the horizontal-axis wind turbines can be further classified as upwind and downwind wind turbines. The majority of horizontal-axis wind turbines in use are upwind turbines, in which the wind rotors face the wind which offers the advantage of avoiding the distortion of the flow field as the wind passes through the wind tower and nacelle (a streamlined housing or tank). For a downwind turbine, wind blows first through the nacelle and tower and then the rotor

blades and this configuration enables the rotor blades to be made more flexible. However, because of the influence of the distorted unstable wakes behind the tower and nacelle, the wind power output generated from a downwind turbine fluctuates. In addition, the unstable flow field may result in more aerodynamic losses and introduce more fatigue loads on the turbine. Furthermore, the blades in a downwind wind turbine may produce higher impulsive or thumping noise.

See also: Mechanical Energy, Wind Turbines.

Wind Turbines – Environmental Impact

Modern wind farms today may contain a large number of large-size wind turbines. Therefore, their impacts on the environment cannot be ignored. One of the impacts is that poorly sited wind energy facilities may block bird migration routes and hurt or kill birds. Though blade rotation speeds are rather low for large wind turbines at their normal operation, the tangential speeds at the blade tips could be higher than 70 meters per second. At such high speeds, birds flying through the blade sweeping areas may be easily hurt or killed by colliding with blades. It is important to evaluate the long-term influence on local geography, seasonal bird abundance, and the species at risk. To reduce the bird death, using bird scares to drive birds away from wind farms has been considered.

Before building a wind farm, a series of environmental assessments have to be completed to avoid bird migration routes and to minimize other environmental impacts. Once the wind farm is built, further monitoring takes place to better understand the ongoing relationship between birds and the wind farm. Building wind farms will change the character of local landscape. Modern large wind turbines are more than 300 feet tall and thus can be seen at a far distance. In practice, the visual effect for local residents is a significant consideration and is always scrutinized for wind projects. To minimize the visual effect, wind turbines usually use neutral colors such as light gray or off-white. Strategies to minimize visual effects involve the spacing, design, and uniformity of turbines, markings or lighting, roads, and service buildings.

With the extensive buildup of wind power plants, the influence of wind turbine noise to the nearby residents becomes an issue that cannot be ignored. Wind turbine noise consists of aerodynamic noise from rotating blades and mechanical vibration noise from gearboxes and generators. For a modern large wind turbine, aerodynamic noise from the blades is considered to be the dominant noise source. There are two components in aerodynamic noise which are (i) airfoil self-noise, that is, the noise produced by the blade in an undisturbed inflow and is caused by the interaction in the boundary layer with the blade trailing edge; and (ii) inflow turbulence noise which is caused by the interaction of upstream atmospheric turbulence with the blade and depends on the atmospheric conditions. Both airfoil self-noise and inflow turbulence noise mechanisms are dependent on a number of parameters such as wind speed, angle of attack, radiation direction, and airfoil shape.

There are a number of techniques for reducing aerodynamic noise produced by wind turbine blades. One technique is to use serrated blades at the trailing edge of the blades which can improve blade aerodynamic characteristics and reduce the noise induced by a Kármán vortex street, which is a repeating pattern of swirling vortices, caused by a process known as vortex shedding, which is responsible for the unsteady separation of flow of a fluid around blunt bodies.

Another technique is to use turbulence generating means, placed on the leeward surface side and at the outer section of the blade, to reduce noise.

Winkler Gasifier

Another gasifier that has had wide commercial use but is now mainly of historical interest is the Winkler gasifier.

Unlike the other gasifiers discussed so far, the Winkler gasifier is a fluidized bed system. It was the first commercial application of fluidized bed technology, and was developed in the late 1920s with the aim of gasifying coal fines, which were cheaper than lump coal. It operates at atmospheric pressure or slightly above, with a bed temperature of around 950°C. Gasification reactions are similar to the Lurgi except that there is less methane formation due

to the lower pressure, and pyrolysis products including tars and oils are decomposed within the gasifier. Being both a low-pressure and low-temperature process, gasification rates are low and residence times of up to 3 hours are required to achieve acceptable conversions. Carbon conversions are, in fact, as low as 60%, partly due to the difficulty in measuring the coal feed rate, and the need to maintain an excess of coal relative to oxygen for safety considerations. In addition, the fluidized bed system cannot handle caking and swelling coals, and the Winkler is really only suitable for use with the highly reactive lignite for which it was originally intended. Consequently, Koppers-Totzek and Lurgi units are replacing the Winkler in commercial applications.

See also: Gasification, Gasifiers.

Winkler Process

The Winkler process is an established process for the gasification of coal. In the process, dried, crushed coal (-8 mesh) is fed to the fluidized bed gasifier through a variable-speed screw feeder whereupon the coal is contacted with steam and oxygen injected near the bottom of the vessel. The upward flow of steam and oxygen maintains the bed in a fluidized state at a temperature of 815 to 980°C (1,600 to 1,800°F) with a pressure that is marginally higher than atmospheric. The high operating temperature reduces the amount of tars and other heavy hydrocarbons in the product.

Approximately 70% of the coal ash is carried over by the gas flow, and the remainder is removed from the bottom of the vessel by screw conveyors. Unreacted carbon contained in the carryover ash is consumed by the injection of supplemental steam and oxygen in the space above the bed. In order to moderate the bed temperature and thereby minimize ash melting, a heat exchange surface is provided in the dilute phase to remove heat and generate steam. The raw gas leaving the gasifier, rich in carbon monoxide and hydrogen, is cooled to approximately 705°C (1,300°F) in a boiler and then passes through (i) a heat exchanger to superheat steam, (ii) a waste heat boiler, and (iii) a cyclone to remove entrained char. Further gas clean-up is affected by wet scrubbers, electrostatic precipitators, and sulfur removal technology.

Wobbe index

The Wobbe index (WI, or Wobbe number, WN) is a number which represents the properties of a stream gas and is the calorific value of a gas divided by the specific gravity. The Wobbe Index is an indicator of the interchangeability of fuel gases such as natural gas, liquefied petroleum gas (LPG), and coal gas. It is frequently defined in the specifications of gas supply and transport utilities.

The Wobbe Index, I_w , is the relationship between the higher heating value and the square root of gas specific gravity:

$$I_w = V_c / \sqrt{G_s}$$

V_c is the higher heating value, or calorific value, and G_s is the specific gravity.

The higher heating value (HHV; also known as the gross calorific value or gross energy) of a fuel is the amount of heat released during combustion by a specified quantity (initially at 25°C), and the products have returned to a temperature of 25°C. The *higher heating value* takes into account the latent heat of vaporization of water in the combustion products, and is useful in calculating heating values for fuels where condensation of the reaction products is practical (e.g., in a gas-fired boiler used for space heat) and assumes all the water component is in liquid state at the end of combustion (in the product of combustion).

The lower heating value (net calorific value, net CV, or LHV) of a fuel is defined as the amount of heat released by combusting a specified quantity (initially at 25°C or another reference state) and returning the temperature of the combustion products to 150°C.

The lower heating value assumes all the water component is in vapor state at the end of combustion (in product of combustion), as opposed to higher heating value which assumes the entire water component in the liquid form of the combustion gas. The lower heating value assumes that the latent heat of vaporization of water in the fuel and the reaction products is not recovered. It is useful in comparing fuels where condensation of the combustion products is impractical, or heat at a temperature below 150°C cannot be put to use.

The Wobbe Index (Table W-6) is used to compare the combustion energy output of different composition fuel gases in an appliance (fire, cooker, etc.). If two fuels have identical Wobbe Indices, then for given pressure and valve settings, the energy output will also be identical. Typically, variations of up to 5% are allowed as these would not be noticeable to the consumer. The Wobbe Index is a critical factor to minimize the impact of the changeover when analyzing the use of synthetic natural gas fuels such as propane-air mixtures.

Table W-6 Wobbe index (kcal/m³) of natural gas and its common constituents.

Gas	Upper Index	Lower Index
Natural gas	12,837	11,597
Methane	12,735	11,452
Ethane	16,298	14,931
Propane	19,376	17,817
n-Butane	22,066	20,336
iso-Butane	21,980	20,247

The Wobbe index is commonly expressed in Btu per standard cubic foot or megajoules per standard cubic meter (1000 BTU/scf = 37.3 MJ/m³). In the case of natural gas, the typical heating value is around 1,050 Btu per cubic foot and the specific gravity is approximately 0.59, giving a typical Wobbe index of 1.367.

There are three ranges or groups of fuel gases that have been internationally agreed based on Wobbe Index which are (i) Group 1, which includes manufactured gases, (ii) Group 2, which covers natural gas, with high and low ranges, and (iii) Group 3, which includes liquefied petroleum gas (LPG).

Combustion equipment is typically designed to burn a fuel gas within a particular family: hydrogen-rich town gas, natural gas, or liquefied petroleum gas. Other flame characteristics and composition limits may determine the acceptability of the replacement gas, e.g., flame speed, yellow tipping due to incomplete combustion, sulfur content, and oxygen content.

Wood

Of all of the alternate energy sources (relative to fossil fuels), the use of wood predates the others and dates from pre-biblical times (pre-4,000 BC). In peace and in war, in the Old and the New World, man first turned to wood for his basic needs and later learned to use advanced science to employ wood as his most sophisticated raw material, being infinitely versatile and an easily renewable source.

The manner in which wood was used by early cultures is difficult to determine, as wood artifacts have largely disappeared. Certainly, the use of wood for fire is one of the first and most significant contributions of this resource to the development of society. No doubt man built early pole structures from the small trees growing along the rivers, and later, he would build more solid structures from planks, turf, mud, and adobe. The Scandinavians developed the basic principles of timber framing which were probably known in Europe in the Bronze Age, and framing eventually became the pre-eminent method of wood building in the Western World, reflecting developments in structural engineering that had been worked out with wood mostly through trial and error.

One of the first uses of wood for water transport was probably a hollowed-out log. Around 4000 BC, the Egyptians were making ships from bundles of reeds and their earliest wooden boats copied the hull frame of the reed boats.

For larger vessels, the Egyptians imported cedar from Lebanon. One reason for the northward expansion of Egypt's influence was to ensure its cedar supply. Records show that the Egyptian shipbuilder could use wood on a grand scale. Queen Hatshepsut's barge, built in 1500 BC to transport granite obelisks from Aswan to Thebes, had a displacement of some 7500 tons, and 30 oar-powered tugs were needed to tow it.

According to Theophrastus, a pupil of Aristotle, there is knowledge of the shipbuilding in Ancient Greece and the ship-building woods are silver fir, fir, and cedar. Silver fir is used for lightness; for merchant ships, fir is used because of its resistance to rot. In Syria and Phoenicia, cedar is used because of the lack of fir.

Technological improvement in land transport was slower than that of water transport. From 7000 B.C. onward, wood sledges were used for heavy loads such as stones, and archeologists reason that the massive stones in the great monument at Stonehenge on Salisbury Plain, England, must have been moved on sledges placed on rollers, which may have inspired the discovery of the wheel. But there is still no record of when and where the wheel was invented, though surely the first axle was made of wood.

Another significant contribution of wood to the ancient world was for war devices. Examples include the catapult, which enabled a man to attack his enemy from a safe distance, the battering ram and scaling ladder, the tortoise, and the siege tower. Although the choice of materials for these purposes was quite limited, the properties of wood made it eminently suitable. High strength and low weight were highly valued characteristics of wood then, just as they are today. These siege engines were integral to the expansion of both Greek and Roman civilizations and of the science, technology, and philosophy that developed under the tutelage of the great thinkers and teachers of the times.

The ancient man was using wood to conquer his world as well as build it and explore it. Then, some unknown woodman in Ancient Greece invented a primitive wooden lathe, and man found himself on the threshold of the age of machines. When he entered that age, he would find ways to make wood work for him to unprecedented degrees. From the basic concept of the lathe and the ability to shape wood to circular symmetry developed new concepts of both materials use and machine development.

In Europe, the water-and-wood phase reached a high plateau around the 16th century. At about this time, the availability of timber diminished. The scarcity was caused by the expansion of agriculture, the increasing use of wood as a structural material and fuel, and from growing demands of the smelting furnaces. To smelt one cannon took several tons of wood. By the 17th century, Europeans were turning to coal for the domestic hearth, and when the secret of smelting metal with coal was discovered, coal became the unique basis for industrial technology until late in the 19th century.

In early 19th century America, a seemingly inexhaustible supply of timber existed. The technology here was geared to exploiting the use of all natural resources to make up for the scarcity in capital and labor. But the technological advances of the 19th century, along with the increasing population, would have a major impact on American forests. Railroads, telegraph lines, charcoal-fueled steel mills, and other industries were consuming immense quantities of wood. The Civil War made a heavy demand – for example, one gun factory alone used 28,000 walnut trees for gun-stocks. During the latter half of the 19th century, the volume of lumber produced each year rose from 4 thousand million board feet to approximately 35 thousand million board feet.

As with many other industries of this time, lumbering was a highly competitive business. Quick profits were the name of the game. This encouraged careless and extravagantly wasteful harvesting and manufacturing methods. The visible devastation that resulted encouraged a new concern for America's forests. Theories were published that purported to prove that the fall of ancient empires, radical changes of climate, and the spread of epidemics could be attributed to deforestation.

However, the wood-and-water phase in the United States reached its own plateau around 1850 and approximately 200 years after that phase had peaked in Europe. The European technology was based on the coal-and-iron complex. Some of the traditional uses of wood – for fuel, pavement, sailing ships, charcoal, and iron smelting – were taken over by coal, steel, and stone. However, demand for timber was maintained as many new uses as possible of wood, for paper, plywood, telegraph and telephone poles, railroad ties, and chemicals, entered the picture. The selection from among competing materials was based partly on cost and availability and partly on properties and performance. It is also noteworthy that such a range of choices coincided with the rapid mechanization and increasing technical complexity of society. Nevertheless, in the late 19th century, the use of wood products had begun to level off. For the time being, most of the country stopped worrying about a timber scarcity. Coal was abundant, and iron and steel could be manufactured.

Up to the latter part of the 19th century, no appreciable systematic research on wood occurred. Wood had been used by early experimenters to make instruments and other research equipment, and early engineers had used it as a

construction material and a material with which to work out engineering problems and designs. Methods for pulping wood to make paper had been worked out by the paper industry, too. Further, both cotton and wood had been used by chemists as a source of cellulose for man-made fibers. This led to work on cellulose acetate reactions with solvents that led to the ability to produce that compound as both film and fiber. These advances provided a base for the subsequent technology of nylon and established the principles by which countless numbers and kinds of linear high polymers can be synthesized.

The carriage business provided an early milestone for a new era of wood research. In 1889, the Carriage Builders Association was concerned about the scarcity of northern oak, a species long preferred for their craft. The builders wondered if southern oak, in plentiful supply, possessed the same desirable characteristics as the northern species. The Division of Forestry of the US Department of Agriculture stepped in to help solve the problem. Its research confirmed that a suitable material could be obtained from the South as well as the North. This incident was an important step toward comprehensive wood research as is known currently. From 1890 to 1910, small amounts of money were appropriated by the Division of Forestry to universities for wood research. Studies of the mechanical properties of wood were begun, along with wood preservation and wood drying studies.

In 1910, the Division of Forestry, in cooperation with the University of Wisconsin, established the world's first comprehensive forest products-laboratory in Madison, Wisconsin, to centralize the federally sponsored wood science efforts in the country. The birth of a full-fledged wood research laboratory could not have happened much earlier. The leaps and bounds science had taken in the 19th century provided the necessary foundation for such a laboratory. Each of the major branches of experimental science made such great progress then that in retrospect, its earlier state seemed rudimentary. Scientists would call this century the Golden Age.

During World War II, wood research covered the whole gamut of possible wartime uses of wood, but after the war the importance of timber products declined, on a relative scale, as the importance of minerals increased, due in part to abundant low-cost energy in the form of coal and then petroleum. It is worth noting, however, that the tonnage of timber products produced in the USA then exceeded that of all metals and plastics combined, just as it does today. So, while timber declined in relative importance and public awareness, it remained the major product of American manufacture.

Currently, low cost and accessible energy can no longer be taken for granted and there are many people, including materials scientists and engineers, who are beginning to appreciate the need for renewable resources like wood. This appreciation is heightened and fed by the fact that the USA finds itself blessed with a timber inventory that is increasing each year. Unfortunately, much of this is not of the large clear sixes and high quality to which humans are accustomed.

On the other hand, the past abundance of timber and the dispersion of the industry have worked against advances in technology for the efficient production, conversion, and use of wood products. Fortunately, and despite its relatively recent origin as a recognized field of study, wood science has had an appreciable effect on wood technology as well as science in general. The study of wood chemistry has contributed to an understanding of the principal components of wood – cellulose and lignin – and their reactions. Early research on hydrolysis of cellulose was prompted by fuel needs in World War I, but contributed much to the knowledge base of this form of chemical reaction. Similarly, research on nitrocellulose was prompted by the needs for explosives. Accompanying studies of saccharification and fermentation are contributing much to scientific knowledge in those areas. Engineering studies of wood as an orthotropic material contributed strongly to the concept of sandwich construction, now commonly used in aircraft design, as well as to the early development of glass-fiber-reinforced plastics in the 1950s and 1960s.

Another research focus is on use of wood for fuel, which still plays a big part in man's existence. Today, approximately half of the world's annual wood harvest is burned for those same products the primitive man valued from his wood fire – heat and light. But much of this is in the less developed countries. In most developed countries, the use of wood for fuel peaked in the last century. But with the energy situation as it is today, even developed countries are turning to wood for fuel. It is renewable, relatively cheap, low in ash content, and negligible in sulfur content.

On the other hand, wood is bulky, has less than half the heat of combustion of fuel oil, and in its green state is heavy to ship. Furthermore, the cost of a wood-burning system may be three to four times that of a gas-burning installation because of fuel storage, handling, and air quality control systems. These drawbacks have kindled interest in production of liquid and gaseous fuels from wood. Much research is devoted to improving existing technology and devising new approaches, but such fuels are still expensive compared with petroleum-based fuels.

Closely related to the conversion of wood to liquid or gaseous fuel is the use of the chemical storehouse that is wood to produce a wide range of silvi-chemicals. Research has shown how to produce useful products from cellulosic

polymers, wood and bark extractives, oleoresins, and pulping liquors. Many processes of these types already form the basis of chemical production on a commercial scale. But the potential to use wood as a chemical feedstock is much greater than has so far been realized. Whole wood can be gasified, liquefied, or pyrolyzed in ways comparable with those used for coal to yield a wide variety of chemicals. Cellulose, as a glucose polymer, can be hydrolyzed to the glucose monomer by acid or enzymes, and the glucose then fermented to ethanol. The ethanol can be used as a fuel or as a source of other important chemicals such as ethylene or butadiene.

As an alternative, the use of glucose as a substrate for fermentation would make a possible production of antibiotics, vitamins, and enzymes. Hemicelluloses can easily be converted to simple sugars which can be used to produce ethanol or furfural, a potential raw material for nylon or other synthetics.

Lignin can be pyrolyzed, hydrogenated, and hydrolyzed to yield phenols, which can be further processed to benzene. Once the technology and economics are feasible, future plants will manufacture a variety of these significant chemicals from wood, now derived from petroleum or other resources.

See also: Lignin, Lignocellulose, Wood Biomass.

Wood – Biomass

Wood logs are the first ever-known energy application of biomass – burning wood for heating and lighting has been known by humanity for millennia. Stem wood is a perfect feedstock for biomass-to-liquids processing, since being a pure wood (a hydrocarbon material), it has negligible content of impurities and harmful substances that have to be removed during gasification compared to, e.g., waste wood.

The wood biomass comprises stem wood from ordinary forestry, dedicated (short-rotation) forestry, as well as various residues and wood wastes. However, two core types of biomass raw material are distinguished: (i) woody biomass and (ii) herbaceous biomass. Currently, woody material accounts for approximately 50% of the total world bioenergy potential. Another 20% is straw-like feedstock, obtained as a by-product from agriculture. However, wood from different sources will exhibit different properties (Table W-7).

Table W-7 Examples of the properties of different types of wood.

Property	Wood	Forest residue	Wood chips	Wood pellets
Proximate analysis				
Ash, % w/w	0.4-0.5	1-3	0.8-1.4	0.4-1.5
Moisture, % w/w	5-60	50-60	20-50	7-12
Volatile matter, % w/w w/	>70	>70	76-86	>70
Ash melting point, °C	1,400-1,700	-	1,000-1,400	>1,120
Elemental analysis				
C, % w/w	48-52	48-52	47-52	48-52
H, % w/w	6.2-6.4	6.0-6.2	6.1-6.3	6.0-6.4
N, % w/w	0.1-0.5	0.3-0.5	<0.3	0.27-0.9
O, % w/w	38-42	40-44	38-45	40
S, % w/w	<0.05	<0.05	<0.05	0.04-0.08
Cl, % w/w	0.01-0.03	0.0-1-0.04	0.02	0.02-0.04
K, % w/w	0.02-0.05	0.1-0.4	0.02	-
Ca, % w/w	0.1-1.5	0.2-0.9	0.04	-

The technical platform chosen for biofuel production is determined in part by the characteristics of the biomass available for processing. The majority of terrestrial biomass available is typically derived from agricultural plants and from wood grown in forests, as well as from waste residues generated in the processing or use of these resources. Today, the primary barrier to utilizing this biomass is generally recognized to be the lack of low-cost processing options capable of converting these polymers into recoverable base chemical components.

At present, wood is the largest single renewable energy source in many countries, especially the countries of the European Union, and accounts for more than half of all renewable energies. The woody biomass comprises stem wood from ordinary forestry, dedicated (short-rotation) forestry, as well as various residues and wood wastes.

In the United States, much of the biomass being used for 1st-generation biofuel production includes agricultural crops that are rich in sugars and starch. Because of the prevalence of these feedstocks, the majority of activity toward developing new products has focused on the bioconversion platform. Bioconversion isolates sugars from biomass, which can then be processed into value-added products. Native sugars found in sugarcane and sugar beet can be easily derived from these plants, and refined in facilities that require the lowest level of capital input. Starch, a storage molecule which is a dominant component of cereal crops such as corn and wheat, is comprised wholly of glucose. Starch may be subjected to an additional processing in the form of an acid- or enzyme-catalyzed hydrolysis step to liberate glucose using a single family of enzymes, the amylases, which makes bioconversion relatively simple. Downstream processing of sugars includes traditional fermentation, which uses yeast to produce ethanol; other types of fermentation, including bacterial fermentation under aerobic and anaerobic conditions, can produce a variety of other products from the sugar stream.

Forest biomass or agricultural residues are almost completely comprised of lignocellulosic molecules (wood), a structural matrix that gives the tree or plant strength and form. This type of biomass is a prime feedstock for combustion, and indeed remains a major source of energy for the world today. The thermochemical platform utilizes pyrolysis and gasification processes to recover heat energy as well as the gaseous components of wood, known as synthesis gas or 'syngas'. Syngas can then be refined into synthetic fuels, including Fischer-Tropsch, methanol, and ethanol, through the process of catalytic conversion.

Lignocellulose is a complex matrix combining cellulose, hemicellulose, and lignin, along with a variable level of extractives. Cellulose is comprised of glucose, a six-carbon sugar, while hemicellulose contains both five- and six-carbon sugars, including glucose, galactose, mannose, arabinose, and xylose. The presence of cellulose and hemicellulose therefore makes lignocellulose a potential candidate for bioconversion. The ability of the bioconversion platform to isolate these components was initially limited, as the wood matrix is naturally resistant to decomposition. Recent advances, however, have made this process more commercially viable. Costs remain higher than for starch-based bioconversion, but there is added potential for value-added products that can utilize the lignin component of the wood.

In order to incorporate all aspects of biofuel production, including the value of co-products and the potential of the industry to diversify their product offering, the biorefinery concept is employed. The biorefinery concept is important because it offers many potential environmental, economic, and security-related benefits to society. Biorefineries provide the option of co-producing high-value, low-volume products for niche markets together with lower-value commodity products, such as industrial platform chemicals, fuels, or energy, which offsets the higher costs that are associated with processing lignocellulose.

The wood biomass comprises stem wood from ordinary forestry, dedicated (short-rotation) forestry, as well as various residues and wood wastes. However, two core types of biomass raw material are distinguished which are (i) woody and (ii) herbaceous. Currently, woody material accounts for approximately 50% of total world bioenergy potential. Another 20% is straw-like feedstock, obtained as a by-product from agriculture.

Residual wood is the material that is a refuse without objective value within a specific context; otherwise, it constitutes a material at the end of its usefulness. Thus, a number of woody materials can be included in the group of residues and waste: thinning and logging residues from forest industry (tops, branches, and small size stems), demolition wood and railway sleepers, fiberboard residues, cutter shavings, and plywood residues. Residual woody material is believed to be a very promising bioenergy resource since it is available at much lower or negligible cost compared to wood logs and short-rotation forestry.

However, the availability of residual woody biomass depends on the primary wood yield and typically accounts for 25 to 45% of all harvested wood on average. The heterogeneous composition of the residual and waste woody

biomass (content of moisture, impurities, etc.) might sometimes preclude its application for biomass-to-liquids production. Hence, preliminary treatment of the residual and waste woody biomass may be necessary, in order to make it appropriate for processing to liquid fuels.

Fireplaces and wood stoves, popular aesthetic accessories of the recent past, are rapidly gaining prominence as primary or supplemental heat sources for homes. The rising costs, and in some instances, actual shortages of conventional home heating energies, have led to greatly increased utilization of wood as a heating fuel.

Firewood, one of nature's most common methods of storing solar energy, is a renewable energy source. It is a relatively clean, efficient, safe energy source having low sulfur content and is generally found throughout the country. Its primary products of combustion are carbon dioxide, water vapor, and ash. The ash content is low – only 1 to 2% by weight – and that which does remain can be used as a worthwhile soil conditioner.

A wood fire is easy to start and produces a large quantity of heat in a short time as well as adding a cheerful atmosphere to the home. An ample air supply to the wood fire is important to ensure complete burning or combustible gases. Wood fires are ideal where heat is required only occasionally, for warming a living area on cool days or for supplying extra heat in extremely cold weather. When considering wood as a primary heat source, several factors must be carefully weighed to ensure satisfactory results and acceptable deficiencies.

Generally, hardwoods which provide long-burning fires contain the greatest total heating value per unit of volume. Softwoods which give a fast burning, cracking blaze are less dense and contain less total heating value per unit of volume.

Wood Chips

Wood chips represent a resource that is currently available from forestry, and one of the largest unexploited categories is wood that needs to be removed from forests to reduce the risk of forest fires. Well over 8 billion dry tons of biomass have been identified by the U.S. Forest Service as needing fuel treatment removal. The amount of this biomass potentially available for bioenergy uses is estimated to be approximately 60 million dry tons annually. This estimate takes into consideration factors affecting forest access, residue recovery, and the desirability of using some of the recoverable biomass for conventional wood products. The fraction that could be available for bioenergy and bioproducts is less than 1% of the total size of the fuel treatment biomass resource. Factors affecting the rate at which this source of material will become available include public opinion toward this type of removal, as well as delivered costs and the extent to which technology is developed for utilizing small diameter wood for products other than bioenergy. The other large, underutilized forest sources of woodchips are logging residues and urban wood residues. In both cases, the relatively high costs of removal, handling, and transportation have not compared favorably to their relatively low value as an energy resource. Also, the compost market could compete for urban wood resources.

Wood chips represent chopped with special facilities (chippers) woody raw material – whole trees (usually soft wood), short-rotation forestry, wood residues (branches, tops, etc.) with particle size 5 to 60 mm. The chips from stem wood and short-rotation forestry are of higher quality and contain fewer impurities than the chips from residual and waste woody material, but conversely, they are also more expensive.

Wood chips are gaining an increasing popularity as they allow utilization of various residual and waste woody materials, which otherwise are not suitable for gasification. By combining different woody materials, the poorer qualities of a given material can be partly compensated with the better properties of another material. In addition, chipping ensures a homogeneous feedstock with guaranteed qualities, which is a mandatory pre-requisite for efficient gasification. Chipping is also energy efficient, as it requires only 1-3% of the energy content of woody biomass on average. The energy cost for wetter raw materials is lower, due to their lower internal friction.

As already mentioned, chipping allows a more complete utilization of woody biomass. On the other hand, the reproduction of forests and the maintenance of high wood yields require leaving in the soil part of the nutrients (nitrogen, phosphate, and potassium), contained in wood. A more complete utilization of forest resources also means a larger removal of nutrients. If this process is not carefully controlled, it can result not only in reduced wood yields but also in destroyed biodiversity and deserted areas. It is therefore of prime significance to find the right

balance between short-term yields and long-term fertility of forest soils. Achieving such a balance is relatively easy in practice, since the largest part of the woody biomass, i.e., of the hydrocarbon content, is bound in stems, while the majority of nutrients are contained in needles and branches. Hence, after felling, the whole trees are often left on the ground for a couple of months. During this period, the needles and small branches fall down, owing to gradual drying, and the nutrients are absorbed by the forest soil.

When chipping fresh wood, the moisture content of chips can be high (45 to -55% w/w). Such high moisture levels can obstruct gasification, so the wetness has to be brought down to 5 to 25%. There are three ways of decreasing the moisture content of woody biomass in general and of wood chips in particular, which can be used also consecutively to optimize the financial and energy costs.

When the whole trees are left on the ground for the needles and the small branches to drop away and to remain in the forest, the stems also dry. If the trees are felled between January and March, when the moisture content of wood is normally at its lowest and then are left for the summer to dry, the moisture content can naturally go down from 50-55% to 35-45%. Besides the advantages of natural drying, leaving woody biomass in outdoor storages may result in weight loss, due to natural biological decomposition and/or insect infection (especially for soft wood species). The rate of biological degradation can be rather high, in particular for wet material in the beginning of the storage period. The decomposition rate depends largely on the particle size – the larger the particles, the lower the rate. In order to prevent great weight losses from insect infections, trees left on the ground should be regularly inspected.

Wood chips can be stored outdoor (in the summer) or indoor (in the winter) near the gasification plant for further drying. The summer outdoor storage is preferred, as it is cheaper – due to their low bulk density, chips need large drying space. The reduction of wetness is similar to that of natural drying of whole trees – from 50% to approximately 30%. Outdoor storage of biomass with moisture content less than 30% is not recommended since it can increase due to rainfall. As already stated, in case of outdoor storage and natural drying of chips, special attention should be paid to the rate of biological degradation. Due to the small size of chips, it can be really high – up to 5% per month for fresh chips or bark in the beginning of the period, later on getting down to 1 to 2%.

- Forced drying of wood biomass: Dedicated drying of woody biomass at gasification plants should be avoided in general, since it reduces their energy efficiency and increases costs. Thus, as much as possible, natural drying is recommended. When natural drying is not sufficient and/or heat, which otherwise is lost, is employed for drying (e.g., heat from fuel synthesis), the application of forced drying is justifiable – it even increases the overall energy efficiency of plants. In any case, the additional benefits should be always set against the additional capital and running costs.

Wood – Combustion

Instead of paying disposal costs, wood combustion for electricity and heat is one way in which forest products companies can utilize their wood residues. However, as with any fire, burning wood fuel creates numerous by-products, some of which may be useful (heat and steam), and others that are undesirable, irritating, or dangerous. Among the deleterious by-products are smoke, containing water vapor, carbon dioxide and other chemicals, and aerosol particulates, including caustic alkali fly ash, which can be an irritating (and potentially dangerous) by-product of partially burnt wood fuel. A major component of wood smoke is fine particles that may account for a large portion of particulate air pollution in some regions.

Typically, wood in a variety of forms, particularly green chips (45% to 50% moisture content on a wet basis), is shipped and maintained at a holding site by the energy plant. Augers or belt conveyors transport the wood chips to the combustor, where they are burned, and the heat of combustion is transferred to a steam or hot water boiler. Steam is converted to electrical power by steam turbines. Excess steam can be used in other plant processes such as, for example, in a dry kiln. Hot water boilers can provide heat to a building through a piping distribution network.

See also: Co-Combustion, Combustion.

Wood – Composition and Properties

Wood consists of cellulose ($C_6H_{10}O_5$), resins, lignin, various inorganic salts, and water. The chemical composition of wood varies from species to species, but is approximately 50% w/w carbon, 42% w/w oxygen, 6% w/w hydrogen, 1% w/w nitrogen, and 1% w/w other elements (mainly calcium, potassium, sodium, magnesium, iron, and manganese) by weight. The quantity of water present has great effect on the heating value and ranges from 25 to 50% in green wood, and from 10 to 20% in air-dried wood.

The cellulose content of wood varies between species in the range of 40-50%. Some lignocellulosic materials can have more cellulose than wood. Cellulose is an organic polymer, consisting solely of units of glucose held together in a straight chain macromolecule. These glucose units are bound together by β -(1,4)-glycoside linkages which establish as the repeat unit for cellulose chains; cellulose must be hydrolyzed to glucose before fermentation to ethanol.

Cellulose is a polysaccharide consisting of a linear chain of several hundred to over ten thousand linked D-glucose units and has the formula $(C_6H_{10}O_5)_n$.

Cellulose

The hydrolysis of cellulose (saccharification) produces its glucose monomers.

Wood cut in the spring and summer contains more water than that cut in the early part of the winter. A cord (8 feet long by 4 feet wide by 4 feet high) of hard wood, such as ash or maple, is approximately equal in heating value to one ton of bituminous coal; soft woods, such as pine and poplar, have less than half this amount. Wood burns with a long flame and makes comparatively little smoke; but its calorific intensity is low, averaging from 3,000 to 4,000 C. per kilo of air-dried wood. It is, however, easily kindled, the fire quickly reaches its maximum intensity, and a relatively small quantity of ash is formed. Wood is too expensive for industrial use, except in a few special cases, where freedom from dirt and smoke is necessary. Of other cellulose materials, shavings, sawdust, and straw are used for fuel in some places. They are bulky and difficult to handle, while their heat value, which depends on the amount of moisture they contain, is seldom more than from one-third to one-half that of good coal. Such waste matter as spent tan-bark and bagasse (crushed sugar cane), and the pulp from sugar beets is sometimes used for fuel for evaporation or for steam generation, but owing to the large amount of moisture they contain, the heat value is low.

When considering the type of wood for use as firewood, several characteristics are important. These include heat value, ease of splitting, weight per unit volume, ease of starting, amount of smoking, and coaling qualities. The moisture content of the wood, the number of knots, and pitch content affect these characteristics of the more common woods used as firewood.

All woods dried to the same moisture content contain approximately the same heat value per pound – from 8,000 to 9,500 BTU for fully dried wood and 5,500 to 8,500 BTU for air-seasoned wood. However, the heat content of any fire depends on wood density, resin, ash, and moisture. A general rule for estimating heat value of firewood is: one cord of well-seasoned hardwood (weighing approximately two tons) burned in an airtight, draft-controlled wood stove with a 55 to 65% efficiency is equivalent to approximately 175 gallons of #2 fuel oil or 225 therms of natural gas consumed in normal furnaces having 65 to 75% efficiencies.

Wood – Fuels from

Woodfuels are included in the sector of forests, woodlands, and trees and include all types of biofuels derived directly and indirectly from trees and shrubs grown on forest and non-forest lands.

The definition of forest is broad and includes land with a minimum tree crown cover of 10%. Woodfuels also include biomass derived from silvi-cultural activities (thinning, pruning, etc.) and harvesting and logging (tops, roots, branches, etc.), as well as industrial by-products derived from primary and secondary forest industries which are used as fuel. They also include woodfuels derived from forest energy plantations.

The conversion of wood into fuel goes mainly first through gasification or hydrolysis followed by downstream fermentation or a Fischer-Tropsch reactor. The most promising technology available today is the production of Fischer-Tropsch (FT) diesel through gasification. It offers high energy efficiency (approximately 50 %) and low carbon dioxide emissions (reduction of approximately 85%).

The production of ethanol is less effective, but ethanol has a high octane number and is therefore used as a petrol fuel additive to improve engine performance, typically added as E5 or E10. The use of higher concentrations blends of ethanol such as E85 is possible, but requires small changes to petrol engines.

The gasification process produces a synthesis gas consisting of mainly carbon monoxide and hydrogen. This gas may be fed into a Fischer-Tropsch (FT) reactor where chain growth takes place, producing a wide range of hydrocarbons, including gasoline and diesel.

The energy yield of this process is approximately 50%, and has been proven in pilot plants. An alternative use of the synthesis gas is to feed it to a fermentation reactor, where a modified bacteria culture digests the synthesis gas and produces ethanol as a product.

The hydrolysis step breaks down the cellulose and hemi-cellulose into fermentable sugars. The fermentation follows conventional technology, but with modifications in order to be able to ferment the C5 sugars. The energy yield of the process is approximately 36%. Pyrolysis and hydro thermal upgrading (HTU) are affected by high upgrading costs to enable use in normal automotive engines.

See also: Biomass, Biomass to Energy, Lignin, Lignocellulose, Wood.

Wood Gasification

Wood gasification is the process of heating wood in an oxygen-starved environment until volatile pyrolysis gases (carbon monoxide and hydrogen) are released from the wood. Depending on the final use of the typically low-energy wood (producer) gas (approximately 150 Btu/ft³), the gases can be mixed with air or pure oxygen for complete combustion and the heat produced transferred to a boiler for energy distribution. Otherwise, the gases can be cooled, filtered, and purified to remove tars (a major concern for any wood gasification process) and particulates and used as fuel for internal combustion engines, microturbines, and gas turbines.

See also: Gasification.

Wood – Hardwood

Hardwood is wood from dicot trees which are usually found in broad-leaved temperate and tropical forests. In temperate and boreal latitudes, they are mostly deciduous, but in the tropics and subtropics, the trees are mostly evergreen. Hardwood (which comes from angiosperm trees) contrasts with softwood (which comes from gymnosperm trees).

Hardwoods have a more complex structure than softwoods and are often much slower growing as a result. The dominant feature separating hardwoods from softwoods is the presence of pores (or vessels). The vessels may show considerable variation in size, shape of perforation plates (simple, scalariform, reticulate, foraminate), and structure of cell wall, such as spiral thickenings.

As the name suggests, the wood from these trees is generally harder than that of softwoods, but there are significant exceptions. In both groups, there is an enormous variation in actual wood hardness, with the range in density in hardwoods completely including that of softwoods; some hardwoods (such as balsa wood) are softer than most softwoods, while yew is an example of a hard softwood.

Hardwoods are employed in a large range of applications, including fuel, tools, construction, and the manufacture of charcoal. Solid hardwood joinery tends to be expensive compared to softwood. In the past, tropical hardwoods

were easily available, but the supply of some species, such as teak and mahogany, is now becoming scarce due to over-exploitation. Hardwoods may be used in a variety of objects, but are most frequently seen in furniture or musical instruments because of their density which adds to durability, appearance, and performance. Different species of hardwood lend themselves to different end uses or construction processes due to the variety of characteristics apparent in different timbers, including density, grain, pore size, growth and fiber pattern, flexibility, and ability to be steam bent.

See also: Softwood, Wood.

Wood Pellets

Pellets are normally of 10-30 mm of length at 8-12 mm of diameter. Notwithstanding the fact that they get an increasing popularity as a solid biofuel for heat and to a lesser extent for power generation, their employment in biomass-to-liquids processes. Pellets are usually produced from powder obtained from various residual biomass (woody and/or herbaceous) and waste, or sawdust. To form the pellets, the powder is usually forced through a matrix under high pressure, followed by immediate cooling for durability and stability. The main advantage of pellets over powder, sawdust, and other residual biomass is the much higher energy density, which significantly reduces transportation, storage, and handling costs per energy unit. The drawback of pellets is the lower energy efficiency compared to powder (2 processes instead of just 1). If dry raw material is used, the energy costs may reduce to that of chips – 1.5-2% of the energy content of pellets. If drying is actually necessary, the energy costs may raise up to 7-13%. Additional 10% can be spent for preliminary crushing of the raw material. With regard to the production of liquids from biomass, pelletizing can be justified only when remote biomass has to be brought to the biomass-to-liquids plant, if no other more cost-effective options are available.

See also: Biomass, Wood.

Wood Powder and Sawdust

Apart from chipping, another option to utilize various residual or waste woody materials is as powder. Wood powder represents fine shredding of woody biomass with particle size below 3 mm, usually approximately 1 mm. This is an important advantage over chips, since the smaller the particle size, the better the gasification. Conversely, the energy consumption of mills is typically much higher than that of chippers. The energy penalty grows exponentially with the reduction of the size of wood powder particles below 1 mm. Wood mills are robust and reliable systems, which can process materials of various quality (including with impurities) and particle size. When demolition wood is shredded, a removal of the metallic contaminants (with magnets) may be necessary before the material enters the mill.

Besides dedicated and energy-expensive milling of various woody materials, feedstock with similar particle size can be obtained also directly – sawdust, which is a residual material from sawmills. Similar to chips, when sawdust is left after processing fresh wood, its moisture content could be high, so pre-drying might be necessary.

See also: Biomass, Wood.

Wood – Softwood

Softwood is usually wood from gymnosperm trees such as pine trees and spruce trees which often reproduce using cones and occasionally nuts. The trees classified as softwoods have needle-like or scale-like leaves that, with a few exceptions, remain on the tree all through the year. Hence, softwood trees are sometimes called evergreens. Botanically, they are known as gymnosperms, and instead of bearing seeds from flowers, gymnosperms have exposed seeds in cones.

Within the softwood and hardwood groups, there is a considerable variation in actual wood hardness, the range of density in hardwoods completely including that of softwoods. Some hardwoods (such as balsa) are

softer than most softwoods, while the hardest hardwoods are much harder than any softwood. In short, the terms softwood and hardwood are archaic with questionable meaning and often belie the properties of the wood.

Softwoods are generally most used by the construction industry and are also used to produce paper pulp and card products. In many of these applications, there is a constant need for density and thickness monitoring and gamma-ray sensors have shown good performance in this case. Certain species of softwood are more resistant to insect attack from woodworm, as certain insects prefer damp hardwood. Softwoods which give a fast burning, cracking blaze are less dense and contain less total heating value per unit of volume.

See also: Wood, Wood – Hardwood.

Wood – Solvent Extractable Material

The structure created by hydrogen bonds results in the typical material properties of the chemical constituents of wood confers insolubility in most solvents. For isolation of, for example, cellulose from wood, a direct nitration of wood yields undegraded cellulose trinitrate, which is soluble in organic solvents. On the other hand, the glycosidic linkages are easily cleaved by strong mineral acids and therefore, cellulose can be hydrolyzed to simple sugars. However, for a complete hydrolysis of cellulose, concentrated acid solutions must be used in order to bring about the necessary swelling and at least a partial destroying of the ordered regions. Furthermore, although native lignin derivatives behave as an insoluble and three-dimensional network, the isolated lignin derivatives exhibit maximum solubility in a variety of solvents including dioxane, acetone, methyl cellosolve, tetrahydrofuran, dimethylformamide, and dimethyl sulfoxide.

More generally, the soluble materials or extractives in wood consist of those components that are soluble in neutral organic solvents and are not only suitable for conversion to alternate fuels but can also continue and expand (if there are minimal economic constraints) the petrochemical industry. The di-chloromethane extractable content of wood is a measure of such substances such as waxes, fats, resins, phyto-sterols and non-volatile hydrocarbon derivatives. The amount of extractives is highly dependent on the seasoning or drying of wood. The ethanol-benzene extractable content of the wood consists of certain other di-chloromethane insoluble components such as low-molecular-weight carbohydrates, salts, and other water-soluble substances. Most water-soluble and volatile compounds are removed during pulping. The extractives reduce pulp yield, increase pulping and bleaching chemical consumption, and create problems such as foaming during paper-making if not removed.

For isolation of the extractives from wood, the different methods can be used. Volatile extractives are represented by high-volatile compounds which can be separated by water distillation. They are mainly composed of mono-terpene derivatives and other volatile terpene derivatives, terpenoid derivatives as well as of many different low molecular compounds. The term *terpenes* typically refers to pure hydrocarbon derivatives, whereas the compounds collectively referred to as *terpenoids* have one or more oxygen-containing functional groups, such as hydroxyl, carbonyl, and carboxylic acid groups in the molecule. The basic structural unit of terpenes is isoprene, and they can be divided into subgroups according to the number of isoprene units linked in a terpene.

Isoprene (2-methyl-1,3-butadiene)

Mono-, sesqui-, di-, tri- and polyterpenoids are the most abundant terpenes in wood. In addition to this classification, terpenes can be generally classified according to the number of rings within a structure, for example, into acyclic, monocyclic, bicyclic, tricyclic, and tetracyclic terpenes. Various polypropylene derivatives are also present in certain wood species in the form of rubber and gutta percha, and, in these macromolecules, the number of isoprene units is high.

Structure of natural rubber and gutta percha

Monoterpenes and monoterpenoids are volatile compounds and contribute substantially to the odor of wood. Monoterpenoids occur mainly in softwood oleoresin, either as hydrocarbons or their derivatives. Monoterpenes represent one of the most important constituents of the resin canal extractives and exudates of softwoods. Although monoterpenes and monoterpenoids are rare in common hardwood species, some of these compounds are minor constituents of the oleoresins of tropical hardwoods.

Sesquiterpenes and sesquiterpenoids represent a wide variety of compounds, and they are found as components of canal resin and of the heartwood deposits of softwoods. Sesquiterpenes and -terpenoids are found in many tropical hardwoods but are rare components of hardwoods from temperate zones. Since these compounds occur usually only in small amounts and are therefore commercially less important.

Diterpenes and diterpenoids constitute a major part of the canal extractives and are of great industrial importance. Diterpenoids can be divided into acyclic, bicyclic, tricyclic, tetracyclic, and macrocyclic structure types. Diterpenoids are present either as hydrocarbons or as derivatives with hydroxyl, carbonyl, or carboxyl groups. They seem to be restricted to softwood species mainly in the form of resin acids, and only some diterpenoids have been found in tropical hardwoods.

Triterpenes and triterpenoids comprise mainly oxygenated derivatives and are traditionally treated as two classes of compounds, i.e., triterpenoids and steroids. Triterpenoids can be roughly divided into three subgroups: tetracyclic lanostane, pentacyclic lupine, and pentacyclic oleanane derivatives. Steroids are similar compound groups comparing with triterpenoids, but they differ from some of tetracyclic terpenoids only by the post-cyclization loss of methyl groups in biosynthesis process from the acyclic squalene precursor. Triterpenoids and steroids occur mainly as fatty acid esters and as glycosides, but also in the free form. Triterpenoids and steroids are common in softwoods and generally in relatively small amounts. A great variety of triterpenes and steroids are also present in many hardwoods of tropical and temperate zones. In both softwood and hardwood, the most prominent compound is sitosterol, which is potential raw material for making wood-based chemicals.

Resin is the name as a collective name for the lipophilic extractives (with the exception of phenolic substances). Resin extractives can be extracted with organic solvents. Water-soluble compounds consist of various phenol derivatives, carbohydrates, glycoside derivatives, and soluble salts, which can be extracted by cold or hot water.

Resins are divided into free acids, e.g., resin acid and fatty acid, and neutral compounds (such as fats and waxes). The resin fraction is soluble in organic solvents but insoluble in water, and therefore, it can be extracted with organic solvents, such as hexane, dichloromethane, diethyl ether, acetone, or ethanol. Different non-polar and polar solvents can be selected for isolation of the certain type of extractives from wood.

The analysis of the extractive material can be made at different levels such as (i) gravimetric determination of total extractives, (ii) determination of different component groups, and (iii) analysis of individual components. Component groups in extracts can be determined by several chromatographic techniques: gas chromatography (GC), high performance liquid chromatography (HPLC), size-exclusion chromatography (SEC), supercritical fluid chromatography (SFC), and thin-layer chromatography (TLC).

See also: Biomass, Wood.

Wood – Thermal Treatment

The thermal treatment of wood can be conveniently subdivided into the following categories: (i) the conventional drying process: for evaporating most moisture at 100 to 130°C (212 to 265°F), (ii) heat treatment of lumber: for increasing the durability, mechanical dimensional stability, and water-repellent characteristics in kilns with superheated steam at 185 to 220°C (365 to 510°F), (iii) torrefaction: a thermal treatment without oxygen at 200–300°C (390 to 570°F) and low particle heating rates (<10°C/min) with a long residence time (>1 minute), and (iv) pyrolysis: a process without oxygen for thermal conversion of wood at 400 to 800°C (750 to 1,470°F).

See also: Pyrolysis, Torrefaction.

Wood – Uses

The past abundance of timber and the dispersion of the industry have worked against advances in technology for the efficient production, conversion, and use of wood products. Fortunately, and despite its relatively recent origin as a recognized field of study, wood science has had an appreciable effect on wood technology as well as science in general. The study of wood chemistry has contributed to an understanding of the principal components of wood – cellulose and lignin – and their relationship to each other.

For example, the moisture content of a living tree varies seasonally and the average values are in the range of 40 to 50% w/w of the total wood mass. The chemical constituents of dry wood species are so-called structural substances and non-structural substances. Structural substances are cellulose, hemicelluloses, and lignin. Non-structural substances are mostly low-molecular-mass compounds, such as extractives, some water-soluble organics, and inorganics (Table W-8).

Table W-8 Interrelationships of the various constituents of wood.

Feedstock	General separation	Primary products	Secondary products
Dry wood			
	High-molecular-weight materials		
		Polysaccharides	
			Cellulose
			Hemicellulose
		Lignin	
	Low-molecular-weight materials	Organic substances	
			Extractable constituents
		Inorganic substances	

In addition, softwood differs typically from hardwood with regard to the chemical composition. Furthermore, the chemistry of the hemicellulose derivatives and lignin also differs in the various types of trees. On the other hand, the cellulose, hemicelluloses, and lignin are not uniformly distributed in wood cells, and their relative mass proportions can vary widely, depending on the morphological region and age of the wood.

Early research on hydrolysis of cellulose was prompted by fuel needs in World War I, but contributed much to the knowledge of this form of chemical reaction. As an example of an early process, the Madison Process as it was described in the 1940s was developed to hydrolyze softwood species, which is particularly valuable for the production of fuels such as ethanol. The hemicellulose sugars were recovered in the form of furfural, and only one stage was required. If hardwood species are used, a two-stage process is more desirable to maximize the recovery of both the hemicellulose and cellulose. High yields of hemicellulose products can be obtained at the milder pre-hydrolysis

conditions compared to the higher temperature required to maximize glucose yields from the cellulose in the second stage.

The several acids hydrolysis processes are now being promoted to produce ethanol from wood, but they do it in different types of equipment at slightly different acid-temperature-time conditions. The stake process uses a horizontal screw reactor. The Iotech process uses a high-pressure, short-time hydrolysis followed by rapid release of pressure. The twin-screw extruder process developed by New York University uses a high-pressure, special reactor design. The plug-flow reactor under study at Dartmouth and another developed by American Can use different methods to pump the wood and acid into the reactor. The New Zealand process under license to Ultra Systems is probably a modern version of Madison Process.

After the hydrolysis of the cellulose, the processes could be identical if the same products were to be recovered. Some of the two-stage processes differ in that the residue from the first stage is delignified with a lignin solvent. This dissolves the lignin to leave only cellulose to be hydrolyzed in the second stage. The lignin is then recovered by distilling off the solvent. This is in contrast to hydrolyzing the first stage residue to solubilize the cellulose and leave the lignin.

Wood is bulky, has less than half the heat of combustion of fuel oil, and in its green state is heavy to ship. Furthermore, the cost of a wood-burning system may be three to four times that of a gas-burning installation because of fuel storage, handling, and air quality control systems. These drawbacks have kindled interest in the production of liquid and gaseous fuels from wood. Much research is devoted to improving existing technology and devising new approaches, but such fuels are still expensive compared with crude oil-based fuels.

Finally, closely related to the conversion of wood to liquid or gaseous fuel is the use of the chemical storehouse that is wood to produce a wide range of *silvichemicals*. Many processes of these types already form the basis of chemical production on a commercial scale. But the potential to use wood as a chemical feedstock is much greater than has so far been realized. Whole wood can be gasified, liquefied, or pyrolyzed in ways comparable with those used for coal to yield a wide variety of chemicals. Cellulose, as a glucose polymer, can be hydrolyzed to the glucose monomer by acid or enzymes, and the glucose then fermented to ethanol. The ethanol can be used as a fuel or as a source of other important chemicals such as ethylene or butadiene. As an alternative, the use of glucose as substrate for fermentation would make possible production of antibiotics, vitamins, and enzymes. Hemicelluloses can easily be converted to simple sugars which can be used to produce ethanol or furfural, a potential raw material for nylon or other synthetics.

Lignin can be pyrolyzed, hydrogenated, and hydrolyzed to yield phenols, which can be further processed to benzene. Once the technology and economics are feasible, future plants will manufacture a variety of these very significant chemicals from wood, now derived from crude oil or other resources.

Charcoal continues to be used as an important industrial source of energy. For example, in Brazil, some 6 million tonnes of charcoal are produced every year for use in the heavy industry, such as steel and alloy production. The industrial demand for charcoal in the last few years has led to new, more efficient, and large-scale technologies, mainly aimed at improving charcoal yield and quality. Furthermore, although fuel wood is mainly a local source of energy, there are signs of an international trade in wood fuel developing between European and North American countries.

The dynamics of wood fuel flow are complex and very site-specific. The development of sustainable wood energy systems remains one of the most critical issues to be addressed by policy makers and community planners. With society giving increasing attention to sustainability issues, in the case of wood energy in both developing and developed countries, economic, environmental, and social issues deserve particular attention.

Woodall-Duckham Process

The Woodall-Duckham process employs a gasifier which is a vertical cylindrical vessel having a rotating grate in the bottom for ash removal. There are three functional zones within the reactor, and these are (i) a water-jacketed gasification zone, (ii) a refractory-lined distillation zone, and (iii) a refractory-lined drying zone.

Upon entering the gasifier, which operates at atmospheric pressure, the coal (0.25 to 1.5 inch) is contacted with upward flowing hot gases from the gasification zone and any moisture present in the coal is driven off by the hot

(120°C; 250°F) gases. The coal then falls into the distillation zone where the volatile matter present is driven off by the ascending hot gas, but since a relatively slow heating rate prevails, negligible cracking of the tar and oil occurs.

The devolatilized char (from noncaking coals) or semicoke (from caking coals) is further heated by the hot gases until the material passes into the gasification zone, where it is contacted countercurrently with steam and oxygen (or air) in a fixed bed whereupon the remaining carbon is mostly gasified. The temperature in the gasification zone may depend on the type of coal being processed but is usually of the order of 1,205°C (2,200°F). In the lower portions of this zone, the descending ash is contacted with incoming steam and air, thereby effecting gas preheating and ash cooling. The ash is removed from the gasifier through a rotating grate, which also serves to distribute the air and steam evenly over the entire cross section of the gasifier.

The product gas from the gasifier is withdrawn at two points in the vessel; the gas withdrawn between the distillation and drying zones is known as clear gas, whereas the gas withdrawn near the top of the vessel is called top gas. Varying the portion of gas withdrawn through the lower tap affords a means of control of the temperature of the distillation zone. As the flow of clear gas is reduced, more hot gas is forced through the distillation zone, thus increasing the temperature.

See also: Gasification, Gasifiers.

Wood Gas

Wood can be used to make both liquid and gaseous fuels. When wood is heated in the absence of air, or with a reduced air supply, it is possible to produce a liquid fuel which can be used in a similar way to conventional oil fuels. It can be used to run internal combustion engines in vehicles or generators. The gas produced from wood is a mixture of hydrogen and carbon monoxide which is similar to the coal gas which was made before the arrival of natural gas from the North Sea. This wood gas can be used in internal combustion engines or in gas turbines which can be used to power generators.

Gasification of wood has the potential for providing all fuel needs for small oil- or gas-fired boilers and supplemental fuel for large boilers. The gasification is carried out at elevated temperatures (500 to 1,500°C, 930 to 2,730°F) and at atmospheric or elevated pressures. The process involves conversion of biomass, which is carried out in the absence of air or with less air than the stoichiometric requirement of air for complete combustion. Partial combustion produces carbon monoxide as well as hydrogen which are both combustible gases. The producer gas can serve in different ways: it can be burned directly to produce heat or used as a fuel for gas engines and gas turbines to generate electricity; in addition, it can also be used as a feedstock (synthesis gas) in the production of chemicals, e.g., methanol.

Wood Smoke

Wood smoke forms when wood is made up of a complex mixture of gases and fine particles (particulate matter, PM). In addition to particle pollution, wood smoke contains several toxic harmful air pollutants including benzene, formaldehyde, acrolein, and polycyclic aromatic hydrocarbon derivatives (PAHs, also known as polynuclear aromatic hydrocarbon derivatives, PNAs).

Wood smoke is by far the most compelling argument against wood heating. In cold climates, a frigid, stagnant air mass traps the smoke close to the ground. In the process of wood combustion, wood vaporizes when heated into gases and tar particles. If the temperature is high enough, the tar particles vaporize into chemicals and carbon particles. If the temperature is higher still and there is oxygen present, the gases and particles burn in bright flames.

Chemically, wood is approximately 50% w/w carbon and the rest is mostly made up of oxygen and hydrogen. When a piece of wood is heated, it starts to smoke and turn black at the same time. This is because the other products vaporize under intense heat faster than the carbon burns, so smoking leaves much of the carbon behind until only charcoal remains. The smoke that vaporizes out of the wood is a cloud of nasty, gooey little droplets of a tar-like liquid. Chemically, these droplets are actually big, gooey, complicated hydrocarbon molecules that take a number of different forms, mostly bad.

When wood is burned correctly in a bright, hot, turbulent fire, what is observed is the tar droplets rising off the wood into a zone of extreme heat where they re-vaporize, undergoing thermal decomposition into (for the most part) gaseous constituents. This leaves carbon dioxide, some carbon monoxide and a number of other gases, water vapor and some not quite completely oxidized hydrocarbon products (typically identified as particulate emissions).

The sentiment that wood smoke, being a natural substance, must be benign to humans is still sometimes heard. It is now well established, however, that wood-burning stoves and fireplaces as well as wild fires and agricultural fires emit significant quantities of known health-damaging pollutants, including several carcinogenic compounds (Naeher *et al.*, 2007). Two of the principal gaseous pollutants in wood smoke, carbon monoxide (CO) and the oxides of nitrogen (NO_x), add to the atmospheric levels of these regulated gases emitted by other combustion sources. Thus, there are two issues related to wood smoke and they are (i) whether or not woodsmoke should be regulated and/or managed separately, even though some of the individual constituents are already regulated in many jurisdictions and (ii) whether or not woodsmoke particles pose different levels of risk than other ambient particles of similar size.

The particulate matter wood smoke is extremely small and therefore is not filtered out by the nose or the upper respiratory system. Instead, these small particles end up deep in the lungs where they remain for months, causing structural damage and chemical changes. The carcinogenic chemicals in wood smoke adhere to these tiny particles, which enter deep into the lungs.

Woody Feedstock

A woody (wood-based) feedstock having properties such as (i) a particle size that is too large, (ii) a particle size that is mixed or a too dissimilar particle size, and (iii) a high content of impurities such as water, leads to a difficult gasification process. Hence, woody biomass (Table W-7) normally undergoes preliminary treatments and transformations into feedstocks, which are more suitable for gasification and further processing. Such feedstocks could be wood chips, sawdust, wood powder, or pellets.

Xylan

Xylan (Figure X-1) is a polymer of xylose with a repeating unit of $C_5H_8O_4$, found in the hemicellulose fraction of biomass and can be hydrolyzed to xylose. The xylan derivatives are composed of β -1,4-linked xylose (a pentose sugar) residues with side branches of α -arabino-furanose and α -glucuronic acids and contribute to cross-linking of cellulose microfibrils and lignin through ferulic acid residues. On the basis of substituted groups, xylan can be categorized into three classes: (i) glucuronoxylan, (ii) neutral arabinoxylan, and (iii) glucuronoarabinoxylan.

Figure X-1 Structure of xylan from hardwood

The variation in structure of the glucan derivatives and the xylan derivatives is due to differences in the amounts of the main chemical constituents of biomass (cellulose, hemicelluloses, and lignin, all of which have different uses) being present in different proportions in the various parts of the plant.

In terms of xylan content, genetics as well as environmental factors affect the chemical composition of the various parts of the plant, and it was found that husk, followed by rind and pith, has the highest sugar (glucan + xylan) content. The term glucan represents diverse glucose polymers that differ in the position of glycosidic bonds, which can be short or long, branched or unbranched, alpha or beta isomers, and soluble or insoluble. On the other hand, the term represents a group of hemicellulose derivatives.

Xylene

Xylene (sometimes referred to as xylol) refers to a mixture of three aromatic hydrocarbon isomers ($CH_3C_6H_4CH_3$) (Figure X-2) which is used as a solvent in the printing, rubber, and leather industries.

Figure X-2 The three isomers of xylene.

Xylene is a clear, colorless, sweet-smelling liquid that is highly flammable. It is usually refined from crude oil. The chemical and physical properties of xylene differ according to the respective isomers (Table X-1). Xylene is also used as an inhalant drug for its intoxicating properties.

Table X-1 The general properties of the xylene isomers.

Common name	Xylene	o-Xylene	m-Xylene	p-Xylene
Systematic name	Dimethylbenzene	1,2-Dimethylbenzene	1,3-Dimethylbenzene	1, 4-Dimethylbenzene
Other names	<i>Xylol</i>	<i>o</i> -Xylol; Ortho-xylene	<i>m</i> -Xylol; Meta-xylene	<i>p</i> -Xylol; Para-xylene
Molecular formula	C_8H_{10}			
Molar mass	106.16 g/mol			
Appearance	Clear, colorless liquid			
Density (phase)	0.864 g/mL (liquid)	0.88 g/mL (liquid)	0.86 g/mL (liquid)	0.86 g/mL (liquid)
Solubility (water)	Practically insoluble			
	Soluble in non-polar solvents such as aromatic hydrocarbons			
Melting point	-47.4°C (-53.3°F)	-25°C (-13°F)	-48°C (-54°F)	13°C (55°F)
Boiling point	138.5°C (281.3°F)	144°C (291°F)	139°C (282°F)	138°C (280°F)
Flash point		17°C (63°F)	25°C (77°F)	25°C (77°F)
Viscosity		0.812 cP @ 20°C	0.62 cP @ 20°C	0.34 cP @ 30°C

Xylose

Xylose (Figure X-3) is a hydrolysis product of xylan, which is the main part of hemicellulose present in all flora, particularly in birch and reed.

**Figure X-3** Simple formula for xylose.

Xylitol has become a popular sweetening agent, particularly because of its anti-carries properties. Xylitol is obtained by catalytic hydrogenation of xylose. Hydrogenation of xylose is industrially carried out in three-phase (semi)batch reactors over suspended Raney nickel catalyst. The traditional approach is based on the analysis of the main components only, although it is known that xylulose, arabinitol, furfural, and xylonic acid can appear as by-products. In order to optimize the reaction conditions of an industrial hydrogenation process, it is, however, necessary to have a kinetic model for the formation of both the main and by-products.

Xylose is reduced on a variety of metal catalysts based on nickel to xylitol. Xylose was hydrogenated into xylitol (Figure X-4), a polyol that is widely employed as food, cosmetic, and pharmaceutical additives.

**Figure X-4** Reduction of xylose.

Xylose Fermentation

The pentose (C5) sugar D-xylose (Figure X-5) comprises approximately 30 to 60% w/w of the total fermentable carbohydrate sugars in hardwood and herbaceous biomass and affords a feedstock for the production of ethanol by fermentation.

Figure X-5 Alternate representations of xylose.

The dextrorotary form of xylose, D-xylose, refers usually to the endogenously occurring form of the sugar in living things.

Microorganisms that rapidly ferment xylose to ethanol at high yields are essential to the development of cost-effective, large-scale xylose to ethanol processes. The ability of certain fungi and bacteria to ferment xylose to ethanol has been recognized for many years. Also, the reduction of xylose by catalytic hydrogenation produces the common food additive sweetener substitute xylitol which is a chemical compound with the formula $C_5H_{12}O_5$ [$HO(CH_2)(CHOH)_3CH_2OH$] and is a colorless or white crystalline solid that is soluble in water.

The efficient fermentation of xylose and other hemicellulose constituents is essential for the development of an economically viable process to produce ethanol from biomass. Xylose fermentation using pentose yeasts has proven to be difficult due to the requirement for oxygen during ethanol production, the acetate toxicity, and the production of xylitol as a by-product.

See: Fermentation.

Yeast

Yeasts are eukaryotic heterotrophic organisms (organisms whose cells have a nucleus enclosed within a nuclear envelope) belonging to fungi. In contrast to other eukaryotes, yeasts possess thick and rigid cell wall. Yeast is also considered as the oldest domesticated organism used for thousands of years for the production of alcoholic beverages and raised bread. As a source of carbon and energy, yeasts are capable of fermenting carbohydrates to, for example, bioethanol.

The use of the yeast in food industry as baker's yeast, fodder yeast, for the beer, wine, and spirit production is of great importance. Modern biotechnologies use yeast for the production of various substances (vitamins, enzymes, antibiotics, amino acids, proteins). It can be genetically modified to gain new and more convenient properties and to produce desired compounds. Being relatively easy to handle (mutant isolation, gene transfer, cultivation) and of known genome, yeast is a suitable model organism for the study of physiological and metabolic processes and genetics of eukaryotes. However, some of the yeast genera belong to pathogens that are hazardous for immunocompromised people.

Yeast can, to a lesser extent, ferment oligosaccharides and polysaccharides. Glycerol, lactic acid, ethanol, methanol, and alkane derivatives can also serve as sources of carbon. The sources of carbon and energy are in most yeasts converted aerobically by glycolysis and citric acid cycle. However, in yeast with predominantly fermentative metabolism, the energy is formed during the fermentation process.

Yeast is one of the most widely used industrial microorganisms worldwide. It is irreplaceable in food and pharmaceutical industry and in some research, technical, and medical areas. Production of biologically active compounds of yeast, its biodegradation activity, and production of food and fodder biomass is also of great importance. In addition to the traditional technologies, yeast finds an ever-increasing application in a number of other fields (such as in the production of organic acids and vitamins). Genetically modified yeast can produce pharmacological formulas for both prevention and treatment.

Bioethanol has been identified as the mostly used biofuel worldwide since it significantly contributes to the reduction of crude oil consumption and environmental pollution. It can be produced from various types of feedstocks such as sucrose, starch, lignocellulosic, and algal biomass through fermentation process by microorganisms. Compared to other types of microorganisms, yeast is the common microbes employed in ethanol production due to its high ethanol productivity, high ethanol tolerance, and ability of fermenting a wide range of sugars. However, there are some challenges in yeast fermentation which inhibit ethanol production such as high temperature, high ethanol concentration, and the ability to ferment pentose (C5) sugars.

Various types of yeast strains have been used in fermentation for ethanol production including hybrid, recombinant, and wild-type yeasts. Yeasts can directly ferment simple sugar derivatives into ethanol, while other type of feedstocks must be converted to fermentable sugars before it can be fermented to ethanol. The common processes involved in ethanol production are pretreatment, hydrolysis, and fermentation. Production of bioethanol during fermentation depends on several factors such as temperature, sugar concentration, pH, fermentation time, agitation rate, and inoculum size. The efficiency and productivity of ethanol can be enhanced by immobilizing the yeast cells.

In addition, yeast can be turned into a producer of higher-molecular-weight alcohol derivatives (such as 1-butanol and iso-butanol), sesquiterpene derivatives (such as farnesene and bisabolene), and fatty acid ethyl esters (biodiesel).

Farnesene

Yellow Cake

Yellow cake (yellowcake, sometimes referred to as also called urania, which is uranium oxide UO_2) is a type of uranium concentrate powder obtained from the solution of a leaching process in an intermediate step in the processing of uranium ore. The production of the yellow cake is a step in the processing of uranium after it has been mined but before fuel fabrication or the uranium enrichment process. Yellow cake concentrates are prepared by various extraction and refining methods, depending on the types of ores. Typically, yellow cake is obtained through the milling and chemical processing of uranium ore, forming a coarse powder that has a pungent odor, is insoluble in water, and contains about 80% uranium oxide, which melts at approximately $2,880^\circ\text{C}$ ($5,215^\circ\text{F}$).

In the process to produce yellow cake, the raw uranium ore is crushed to a fine powder to produce pulped ore which is further processed with concentrated acid, alkaline, or peroxide solutions to leach out the uranium. After drying and filtering, the product is yellow cake.

Yellow cake is used in the preparation of uranium fuel for use in a nuclear reactor for which it is smelted into purified uranium oxide (UO_2) to be used in fuel rods for use in a pressurized heavy water reactor as well as in other systems that use natural non-enriched uranium.

Purified uranium can also be enriched to uranium-235 (U-235 , ^{235}U) by a process in which the uranium oxides are combined with fluorine to form uranium hexafluoride (UF_6) after which isotope separation is carried out by the process of gaseous diffusion or in a gas centrifuge. The result is a low-enriched uranium is can produce that contains up to 20% w/w ^{235}U that is suitable for use in most large civilian electric-power reactors. With further processing, highly enriched uranium is obtained which contains 20% w/w or more ^{235}U that is suitable for use in compact nuclear reactors – that is typically used to power naval warships and submarines. Further processing can yield weapons-grade uranium (which typically has levels of ^{235}U levels above 90%, which is suitable for use in nuclear weapons).

Yellow Flax

The yellow flax (or golden flax, *Linum flavum*) is a species of flowering plant in the family Linaceae that is native to central and southern Europe. It is an erect, woody perennial that grows up to approximately 12 inches tall by 8 inches broad with dark green, with semi-evergreen leaves, and terminal clusters of bright yellow, five-petalled flowers in the Spring.

The oil contains omega-3 fatty acids and has been shown to have several health benefits, such as reduced blood pressure and improved regularity as well as a source of liquid fuels, such as biodiesel.

See: Flax and Flaxseed Oil, Linseed Oil.

Yellow Grease

Yellow grease (sometimes referred to as used vegetable oil or waste vegetable oil) is a term from the rendering industry – usually means used frying oils from deep fryers and restaurants' grease traps; can also refer to lower-quality grades of tallow from rendering plants. Yellow grease contains spent cooking oils derived from industrial- or

commercial-scale cooking operations. Thus, yellow grease is used cooking oil whose quality has degraded due to the oxidation, polymerization, or hydrolysis process.

Yellow grease is used cooking oil whose quality has degraded due to the oxidation, polymerization, or hydrolysis process. In previous studies, yellow grease refining had been conducted either by adsorption or by using membrane technology. However, adsorption is a method that is commonly used in refining yellow grease and is the process of choice because the process is easy to perform, and usually is effective in reducing free fatty acid in yellow grease.

Zeolite

A zeolite is a crystalline aluminosilicate used as a catalyst and having a particular chemical and physical structure.

Zeolites provide the cracking function in many hydrocracking catalysts, as they do in fluid catalytic cracking catalysts. The zeolites are crystalline aluminosilicates, and in almost all commercial catalysts today, the zeolite used is faujasite. Pentasil zeolites, including silicalite and ZSM-5, are also used in some catalysts for their ability to crack long chain paraffins selectively. Typical levels are 25 to 50% w/w zeolite in the catalysts, with the remainder being the hydrogenation component and a silica (SiO_2) or alumina (Al_2O_3) binder. The exact recipes are guarded as trade secrets.

Typical naturally occurring zeolites include *analcite* (also called *analcime*) $\text{Na}(\text{AlSi}_2\text{O}_6)$, and *faujasite* $\text{Na}_2\text{Ca}(\text{AlO}_2)_2(\text{SiO}_2)_4 \cdot \text{H}_2\text{O}$ that is the structural analog of the synthetic *zeolite X* and *zeolite Y*. *Sodalite* $(\text{Na}_8[(\text{Al}_2\text{O}_2)_6(\text{SiO}_2)_6]\text{Cl}_2)$ contains the truncated octahedral structural unit known as the *sodalite cage* that is found in several zeolites. The corners of the faces of the cage are defined by either four or six Al/Si atoms, which are joined together through oxygen atoms. The zeolite-structure is generated by joining *sodalite* cages through the four-Si/Al rings, so enclosing a cavity or *super cage* bounded by a cube of eight *sodalite* cages and readily accessible through the faces of that cube (*channels* or *pores*). Joining *sodalite* cages together through the six-Si/Al faces generates the structural frameworks of faujasite, zeolite X, and zeolite Y. In zeolites, the effective width of the pores is usually controlled by the nature of the cation (M^+ or M^{2+}).

Zeolite catalysts can vary in their framework: isomorphous substitution, cation exchange, impregnation, and intercalation. The silicon-to-aluminum ratio (Si/Al ratio) represents the amount of isomorphous substitution in an aluminosilicate zeolite, with a typical range of 1-5. The Si/Al ratio varies, depending on the zeolite. ZSM-5, for example, has a high Si/Al ratio (10-100), while the lowest or the minimum Si/Al ratio possible for an aluminosilicate zeolite is 1. Lowenstein's rule states that there can be no Al-O-Al tetrahedron linkages in the frameworks of zeolites. Zeolites with the faujasite structure, i.e., X and Y, demonstrate Lowenstein's rule: zeolite Y has a Si/Al ratio greater than 1.5, whereas zeolite X has a Si/Al ratio in the range 1-1.5.

Cation-exchange treatment is therefore usually repeated several times using a fresh solution of the cations for exchange in order to achieve a complete exchange. The process of cation-exchange is reversible and is dependent on the concentration of cations in the solution, catalyst proportions, and the zeolite itself. Complete ion-exchange is possible using a simple apparatus.

Zeolite catalysts are mostly used as solid acids or as solid support species for reactions involving transformations of hydrocarbons. The acidity of zeolites (active Brønsted sites, as proton donors) can be increased by cation-exchange within the zeolite channels using ammonium ions and then calcination (Equations 1.2 and 1.3) or using certain polyvalent cations.

The solid becomes highly acidic after an ammonium exchanged zeolite is heated to remove ammonia (NH_3). The protons are mobile between the anionic sites at high temperature (approximately 200°C , 390°F). At even higher temperature (approximately 500°C , 930°F), the removal of water (as vapor) from the solid leads to Lewis acid site

formation (characterized as electron pair acceptor). The formation of such Lewis acid sites enables the catalyst to become more efficient for reactions involving Lewis acid catalysis.

The geometric characteristics of the zeolites are responsible for their special properties, which are particularly attractive to the refining industry. Specific zeolite catalysts have shown up to 10,000 times more activity than the so-called conventional catalysts in specific cracking tests. The mordenite-type catalysts are particularly worthy of mention since they have shown up to 200 times greater activity for hexane cracking in the temperature range 360 to 400°C (680 to 750°F).

Other zeolite catalysts have also shown remarkable adaptability to the refining industry. The resistance to deactivation of the type Y zeolite catalysts containing either noble or non-noble metals is remarkable, and a catalyst life of up to 7 years has been obtained commercially in processing heavy gas oils in the Unicracking-JHC processes. The operating life depends on the nature of the feedstock, the severity of the operation, and the nature and extent of operational upsets. Gradual catalyst deactivation in commercial use is counteracted by incrementally raising the operating temperature to maintain the required conversion per pass. The more active a catalyst, the lower the temperature required. When processing for gasoline, lower operating temperatures have the additional advantage that less of the feedstock is converted to *iso*-butane.

Zinc Oxide Process

Zinc oxide is also used for hydrogen sulfide removal from the gas stream. The zinc oxide media particles are extruded cylinders 3–4 mm in diameter and 4–8 mm in length. This uniform sizing allows for relatively accurate pressure drop calculations in designing reactors. The general reaction of zinc oxide with hydrogen sulfide is:

At increased temperatures 205 to 370°C (400 to 700°F), zinc oxide has a rapid reaction rate, therefore providing a short mass transfer zone, resulting in a short length of unused bed and improved efficiency. At operating temperatures, the zinc oxide sorbent has a maximum sulfur loading of 0.3 to 0.4 kg sulfur/kg sorbent. In large industrial plants, this process achieves a high degree of efficiency, as the spent zinc oxide bed can be used for metal and sulfur recovery.

Generally, the iron oxide process is suitable only for small-to-moderate quantities of hydrogen sulfide. Approximately 90% v/v of the hydrogen sulfide can be removed per bed, but bed clogging by elemental sulfur occurs and the bed must be discarded, and the use of several beds in series is not usually economical. The removal of larger amounts of hydrogen sulfide from gas streams requires a continuous process, such as the Ferrox process or the Stretford process. The *Ferrox process* is based on the same chemistry as the iron oxide process except that it is fluid and continuous.

The Stretford process employs a solution containing vanadium salts and anthraquinone disulfonic acid.

See Gas Cleaning.

Zinc Oxide Slurry Process

The zinc oxide slurry process consists of a simple vertical bubble contactor with the gas providing sufficient agitation to keep zinc oxide particles in suspension in addition to a dispersant:

The majority of the hydrogen sulfide is converted to zinc sulfide. However, zinc mercaptide is a minor product and will form sludge in the reactor which can contribute to foaming.

The Chemsweet process uses zinc acetate, dispersants, and antifoam additives to stabilize the process. The addition of zinc acetate establishes a more controlled reaction. Zinc acetate dissolves to equilibrium to produce zinc ions, which then react with H_2S yielding zinc sulfide and acetic acid. The addition of acetic acid causes more zinc to dissociate, thereby controlling the concentration of zinc ions in solution. While a zinc slurry plant can be easy to operate and install, the high cost of the reactant and difficulty of disposing zinc sulfide wastes make it less attractive. The spent media can be disposed of in an industrial landfill only after passing leachate tests. If the leachate contains more than 20 ppm of zinc and zinc compounds, then it must be treated as a hazardous waste.

Conversion Factors

1. Length Conversions

1 inch = 25.4 mm

1 foot = 0.3048 meter

1 yard = 0.9111 meter

1 mile = 1.609 kilometer

2. Concentration Conversions

1 part per million (1 ppm) = 1 microgram per liter (1 $\mu\text{g/L}$)

1 microgram per liter (1 $\mu\text{g/L}$) = 1 milligram per kilogram (1 mg/kg)

1 microgram per liter ($\mu\text{g/L}$) $\times 6.243 \times 10^8 = 1$ lb per cubic foot (1 lb/ft³)

1 microgram per liter (1 $\mu\text{g/L}$) $\times 10^{-3} = 1$ milligram per liter (1 mg/L)

1 milligram per liter (1 mg/L) $\times 6.243 \times 10^5 = 1$ pound per cubic foot (1 lb/ft³)

1 gram mole per cubic meter (1 g mol/m³) $\times 6.243 \times 10^5 = 1$ pound per cubic foot (1 lb/ft³)

10,000 ppm = 1% w/w

1 ppm hydrocarbon in soil $\times 0.002 = 1$ lb of hydrocarbons per ton of contaminated soil

3. Density

1 pound per cubic foot = 16.03 kilograms per cubic meter

4. Weight Conversion

1 ounce (1 oz) = 28.3495 grams (28.3495 g)

1 pound (1 lb) = 0.454 kilogram

1 pound (1 lb) = 454 grams (454 g)

1 kilogram (1 kg) = 2.20462 pounds (2.20462 lb)

1 stone (English, 1 st) = 14 pounds (14 lb)

1 ton (US; 1 short ton) = 2,000 lbs

1 ton (English; 1 long ton) = 2,240 lbs

1 metric ton = 2204.62262 pounds

1 tonne = 2204.62262 pounds

5. Temperature Conversions

$^{\circ}\text{F} = (^{\circ}\text{C} \times 1.8) + 32$

$^{\circ}\text{C} = (^{\circ}\text{F} - 32)/1.8$

$(^{\circ}\text{F} - 32) \times 0.555 = ^{\circ}\text{C}$

Absolute zero = -273.15°C

Absolute zero = -459.67°F

6. Area

1 square centimeter (1 cm²) = 0.1550 square inches

1 square meter (1 m²) = 1.1960 square yards

1 square kilometer (1 km²) = 0.3861 square miles

1 square inch (1 inch²) = 6.4516 square centimeters = 645.2 square millimeters

1 square foot (1 ft²) = 0.0929 square meters

1 square yard (1 yd^2) = 0.8361 square meters
 1 acre = 4046.9 square meters
 1 hectare = 2.4711 acres
 1 square mile (1 mi^2) = 2.59 square kilometers

7. Volume Conversions

1 cubic inch = 16.39 cubic centimeters
 1 cubic foot = 0.028 cubic meters = 28.32 liters
 1 cubic yard = 0.7646 cubic meters = 764.6 liters
 1 UK gallon = 1 Imperial gallon = 4.546 liters
 1 US gallon = 3.785 liters

8. Nutrient Conversion Factor

1 pound phosphorus $\times 2.3$ ($1 \text{ lb P} \times 2.3$) = 1 pound phosphorous pentoxide ($1 \text{ lb P}_2\text{O}_5$)
 1 pound potassium $\times 1.2$ ($1 \text{ lb K} \times 1.2$) = 1 pound potassium oxide ($1 \text{ lb K}_2\text{O}$)

9. Sludge Conversions

1,700 lbs wet sludge = 1 yd^3 wet sludge
 1 yd^3 sludge = wet tons/0.85
 Wet tons sludge $\times 240$ = gallons sludge
 $1 \text{ wet ton sludge} \times \% \text{ dry solids}/100 = 1 \text{ dry ton of sludge}$

10. Other Conversions

14.7 pounds per square inch (14.7 psi) = 1 atmosphere (1 atm)
 $1 \text{ kilopascal (kPa)} \times 9.8692 \times 10^{-3} = 14.7 \text{ pounds per square inch (14.7 psi)}$
 $1 \text{ yd}^3 = 27 \text{ ft}^3$
 1 US gallon of water = 8.34 lbs
 1 Imperial gallon of water = 10 lbs
 $1 \text{ yd}^3 = 0.765 \text{ m}^3$
 1 acre-inch of liquid = 27,150 gallons = 3.630 ft^3
 $1 \text{ ft depth in 1 acre (in-situ)} = 1,613 \times (20 \text{ to } 25 \% \text{ excavation factor}) = \sim 2,000 \text{ yd}^3$
 1 yd^3 (clayey soils-excavated) = 1.1 to 1.2 tons (US)
 1 yd^3 (sandy soils-excavated) = 1.2 to 1.3 tons (US)

About the Author

Dr. James G. Speight has doctorate degrees in Chemistry, Geological Sciences, and Petroleum Engineering and is the author of more than 90 books in petroleum science, petroleum engineering, biosciences, and environmental sciences as well as books relating to ethics and ethical issues.

Dr. Speight has more than fifty years of experience in areas associated with (i) the properties, recovery, and refining of reservoir fluids, (ii) conventional petroleum, heavy oil, and tar sand bitumen, (iii) the properties and refining of natural gas, gaseous fuels, crude oil quality, (iv) the production and properties of petrochemicals from various sources, (v) the properties and refining of biomass, biofuels, biogas, and the generation of bioenergy, (vi) reactor and catalyst technology, and (vii) the environmental and toxicological effects arising from the use of energy sources. His work has also focused on safety issues, environmental effects, remediation, reactors associated with the production and use of fuels and biofuels, process economics, as well as ethics in science and engineering and in ethics in the universities.

Although he has always worked in private industry which focused on contract-based work, Dr. Speight has served as a Visiting Professor in the College of Science, University of Mosul (Iraq), Visiting Professor in Chemical Engineering at the Technical University of Denmark, and the University of Trinidad and Tobago as well as adjunct appointments at various universities. He has also served as a thesis examiner for more than 25 theses.

As a result of his work, Dr. Speight has been honored as the recipient of the following awards:

- Diploma of Honor, United States National Petroleum Engineering Society. *For Outstanding Contributions to the Petroleum Industry*, 1995.
- Gold Medal of the Russian Academy of Sciences. *For Outstanding Work in the Area of Petroleum Science*. 1996.
- Einstein Medal of the Russian Academy of Sciences. *In recognition of Outstanding Contributions and Service in the field of Geologic Sciences*. 2001.
- Gold Medal - Scientists without Frontiers, Russian Academy of Sciences. *In recognition of His Continuous Encouragement of Scientists to Work Together across International Borders*. 2005.
- Gold Medal – Giants of Science and Engineering, Russian Academy of Sciences. *In recognition of Continued Excellence in Science and Engineering*. 2006.
- Methanex Distinguished Professor, University of Trinidad and Tobago. *In Recognition of Excellence in Research*. 2007. In 2018, he received the American Excellence Award for Excellence in Client Solutions from the United States Institute of Trade and Commerce, Washington, DC.

Check out these other related titles from Scrivener Publishing

Green Energy: Solar Energy, Photovoltaics, and Smart Cities, edited by Suman Lata Tripathi and Sanjeevikumar Padmanaban, ISBN 9781119760764. Covering the concepts and fundamentals of green energy, this volume, written and edited by a global team of experts, also goes into the practical applications that can be utilized across multiple industries, for both the engineer and the student. **NOW AVAILABLE!**

Microgrid Technologies, edited by C. Sharmeela, P. Sivaraman, P. Sanjeevikumar, and Jens Bo Holm-Nielsen, ISBN 9781119710790. Covering the concepts and fundamentals of microgrid technologies, this volume, written and edited by a global team of experts, also goes into the practical applications that can be utilized across multiple industries, for both the engineer and the student. **NOW AVAILABLE!**

Energy Storage, edited by Umakanta Sahoo, ISBN 9781119555513. Written and edited by a team of well-known and respected experts in the field, this new volume on energy storage presents the state-of-the-art developments and challenges in the field of renewable energy systems for sustainability and scalability for engineers, researchers, academicians, industry professionals, consultants, and designers. **NOW AVAILABLE!**

Biofuel Cells, Edited by Inamuddin, Mohd Imran Ahamed, Rajender Boddula, and Mashallah Rezakazemi, ISBN 9781119724698. This book covers the most recent developments and offers a detailed overview of fundamentals, principles, mechanisms, properties, optimizing parameters, analytical characterization tools, various types of bio-fuel cells, edited by one of the most well-respected and prolific engineers in the world and his team. **COMING IN SUMMER 2021**

Biodiesel Technology and Applications, Edited by Inamuddin, Mohd Imran Ahamed, Rajender Boddula, and Mashallah Rezakazemi, ISBN 9781119724643. This outstanding new volume provides a comprehensive overview on biodiesel technologies, covering a broad range of topics and practical applications, edited by one of the most well-respected and prolific engineers in the world and his team. **COMING IN SUMMER 2021**

Energy Storage 2nd Edition, by Ralph Zito and Haleh Ardibili, ISBN 9781119083597. A revision of the groundbreaking study of methods for storing energy on a massive scale to be used in wind, solar, and other renewable energy systems. **NOW AVAILABLE!**

Hybrid Renewable Energy Systems, edited by Umakanta Sahoo, ISBN 9781119555575. Edited and written by some of the world's top experts in renewable energy, this is the most comprehensive and in-depth volume on hybrid renewable energy systems available, a must-have for any engineer, scientist, or student. **NOW AVAILABLE!**

Progress in Solar Energy Technology and Applications, edited by Umakanta Sahoo, ISBN 9781119555605. This first volume in the new groundbreaking series, *Advances in Renewable Energy*, covers the latest concepts, trends, techniques, processes, and materials in solar energy, focusing on the state-of-the-art for the field and written by a group of world-renowned experts. **NOW AVAILABLE!**

A Polygeneration Process Concept for Hybrid Solar and Biomass Power Plants: Simulation, Modeling, and Optimization, by Umakanta Sahoo, ISBN 9781119536093. This is the most comprehensive and in-depth study of the theory and

practical applications of a new and groundbreaking method for the energy industry to “go green” with renewable and alternative energy sources. *NOW AVAILABLE!*

Nuclear Power: Policies, Practices, and the Future, by Darryl Siemer, ISBN 9781119657781. Written from an engineer’s perspective, this is a treatise on the state of nuclear power today, its benefits, and its future, focusing on both policy and technological issues. *NOW AVAILABLE!*

Zero-Waste Engineering 2nd Edition: A New Era of Sustainable Technology Development, by M. M. Kahn and M. R. Islam, ISBN 9781119184898. This book outlines how to develop zero-waste engineering following natural pathways that are truly sustainable using methods that have been developed for sustainability, such as solar air conditioning, natural desalination, green building, chemical-free biofuel, fuel cells, scientifically renewable energy, and new mathematical and economic models. *NOW AVAILABLE!*

Sustainable Energy Pricing, by Gary Zatzman, ISBN 9780470901632. In this controversial new volume, the author explores a new science of energy pricing and how it can be done in a way that is sustainable for the world’s economy and environment. *NOW AVAILABLE!*

Sustainable Resource Development, by Gary Zatzman, ISBN 9781118290392. Taking a new, fresh look at how the energy industry and we, as a planet, are developing our energy resources, this book looks at what is right and wrong about energy resource development. This book aids engineers and scientists in achieving a true sustainability in this field, both from an economic and environmental perspective. *NOW AVAILABLE!*

The Greening of Petroleum Operations, by M. R. Islam *et al.*, ISBN 9780470625903. The state of the art in petroleum operations, from a “green” perspective. *NOW AVAILABLE!*

Emergency Response Management for Offshore Oil Spills, by Nicholas P. Cheremisinoff, PhD, and Anton Davletshin, ISBN 9780470927120. The first book to examine the Deepwater Horizon disaster and offer processes for safety and environmental protection. *NOW AVAILABLE!*

Biogas Production, Edited by Ackmez Mudhoo, ISBN 9781118062852. This volume covers the most cutting-edge pretreatment processes being used and studied today for the production of biogas during anaerobic digestion processes using different feedstocks, in the most efficient and economical methods possible. *NOW AVAILABLE!*

Bioremediation and Sustainability: Research and Applications, Edited by Romeela Mohee and Ackmez Mudhoo, ISBN 9781118062845. Bioremediation and Sustainability is an up-to-date and comprehensive treatment of research and applications for some of the most important low-cost, “green,” emerging technologies in chemical and environmental engineering. *NOW AVAILABLE!*

Green Chemistry and Environmental Remediation, Edited by Rashmi Sanghi and Vandana Singh, ISBN 9780470943083. Presents high quality research papers as well as in depth review articles on the new emerging green face of multidimensional environmental chemistry. *NOW AVAILABLE!*

Bioremediation of Petroleum and Petroleum Products, by James Speight and Karuna Arjoon, ISBN 9780470938492. With petroleum-related spills, explosions, and health issues in the headlines almost every day, the issue of remediation of petroleum and petroleum products is taking on increasing importance, for the survival of our environment, our planet, and our future. This book is the first of its kind to explore this difficult issue from an engineering and scientific point of view and offer solutions and reasonable courses of action. *NOW AVAILABLE!*
